$$\lambda_l := \lim_{q \searrow 0} P(X_2 \leq F_2^{-1}(q) | X_1 \leq F_1^{-1}(q)) \quad (28)$$

If $\lambda_u > 0$, X_1 and X_2 are called *upper tail dependent*, while for $\lambda_u = 0$ they are *asymptotically independent* in the upper tail; this applies analogously for λ_l . For continuous cdf's, Bayes' rule gives

$$\lambda_l = \lim_{q \searrow 0} \frac{C(q, q)}{q} \quad (29)$$

and

$$\lambda_u = 2 + \lim_{q \searrow 0} \frac{C(1-q, 1-q) - 1}{q} \quad (30)$$

A Gaussian copula has no tail dependence if the correlation is not equal to 1 or -1 . For the bivariate t -distribution

$$\lambda_l = \lambda_u = 2t_{v+1} \left(-\sqrt{\frac{(v+1)(1-\rho)}{1+\rho}} \right) \quad (31)$$

provided $\rho > -1$. Note that even for zero correlation this copula shows tail dependence.

Tail dependence is a key quantity for joint quantile exceedances; see Example 5.34 in [14]: a multivariate Gaussian distribution will give a much smaller probability to the event that all returns from a portfolio are below the 1% quantiles of their respective distributions than a multivariate t -distribution. This is because of the difference in the tail dependence.

Association

A relatively stronger concept than correlation is the so-called association introduced in [6]. If $\text{Cov}(X, Y) \geq 0$, then one would consider X and Y as somehow associated. If, moreover, $\text{Cov}(f(X), g(Y)) \geq 0$ for all pairs of nondecreasing functions f, g , they would be considered more strongly associated. If $\text{Cov}(f(X, Y), g(X, Y)) \geq 0$ for all pairs of functions f, g which are nondecreasing in each argument, an even stronger dependence holds. Random variables $X_1, \dots, X_d =: \mathbf{X}$ are called *associated* if $\text{Cov}(f(\mathbf{X}), g(\mathbf{X})) \geq 0$ for all f, g that are nondecreasing and the covariance exists. Examples of associated rv's include independent rv's, positively correlated normal variables, and also the generalized exponential distribution turning up in the Marshall–Olkin copula.

Sampling from Copulas

Consider given marginals $F_1, \dots, F_d$ and a given copula C . The first step is to simulate $(U_1, \dots, U_d)$ with uniform marginals and copula C . By equation (3), the vector $(F_1^{-1}(U_1), \dots, F_d^{-1}(U_d))$ has copula C and the desired marginals.

If the copula is inherited from a multivariate distribution, the task reduces to simulating this multivariate distribution, for example, Gaussian or t -distribution.

If the copula is Archimedean, this task is more demanding and we refer the reader to [14], Algorithm 5.48 for details.

Conclusion

On one hand, copulas are a very general tool to describe dependence structures and have been successfully applied in many cases. However, the immense generality is also a drawback in many applications and also the static characteristic of this measure of dependence has been criticized; see the referenced literature. Obviously, the application of copulas has been a great success to a number of fields, and they are a frequently used concept especially in finance. They serve as an excellent tool for calibrating dependence structures or stress testing portfolios or other products in finance and insurance as they allow to interpolate between extreme cases of dependence.

Literature

The literature on copulas is growing fast. The vital article on copulas **Copulas in Insurance** by P. Embrechts gives an excellent overview of the literature and applications. An introduction to copulas that extends this note in many ways may be found in [20]. For a detailed exposition of copulas with different applications in view, we refer the reader to [4, 14, 19]. Reference [2] gives additional examples and [13] analyzes extreme financial risks. Estimation of copulas is discussed in [14], Section 5.5, [1] and [10]. For an in-depth study of copulas consider [11, 18]. Interesting remarks of the history and the development of copulas may be found in [7]. For more details on Marshall–Olkin copulas, in particular the multivariate ones, see [4, 18]. In the modeling of Lévy processes (see **Lévy Processes**) one considers dependency of jumps where the measure is no longer a probability measure. This leads to the development of so-called Lévy copulas; compare [12] and **Lévy Copulas**. The pitfalls mentioned with linear correlation are discussed in detail in [5] or [14 Chapter 5.2.1]. For a discussion on the general difficulties in the application of copulas, we refer the reader to [9, 16].

End Notes

^aAlthough standard, it is not necessary to consider uniform marginals (see **Copulas in Insurance**).

^bOne example is the exponential distributions whose multivariate extension leads to the Marshall–Olkin copula, introduced in the following paragraph.

^cSee, for example [14], Proposition 5.2.

^dSee [14], Example 5.21, for a counterexample.

^eFor a rv X with continuous cdf F , the rv $F(X)$ is standard uniform, see Section 1.

^fSee **Correlation Risk**.

^gFor generating the Clayton copula, it would be sufficient to use $(u^{-\theta} - 1)$ instead of $\theta^{-1}(u^{-\theta} - 1)$ as generator. However, for $\theta < 0$, this function is increasing and the above result would not be applicable.

^hCompare [14], Theorem 5.36. ρ_S and ρ_τ for elliptic distributions are also covered.

Correlation Risk

Correlation

Correlation is a well-known concept for measuring the linear relationship between two or more variables. It plays a major role in a number of classical approaches in finance: the capital asset pricing model (see **Capital Asset Pricing Model**) as well as arbitrage pricing theory (APT) rely on correlation as a measure for the dependence of financial assets (see [4]). In the multivariate Black–Scholes model correlation of the log-returns is used as a measure of the dependence between assets, [2, 5, 14]. The main reason for the importance of correlation in these frameworks is that the considered random variables (rvs) obey—under an appropriate transformation—a multivariate normal distribution. Correlation is moreover a key driver in portfolio credit models, and the term *default correlation* has been coined for this. Correlation as a measure of dependence fully determines the dependence structure for normal distributions and, more generally, elliptical distributions while it fails to do so outside this class. Even within this class, correlation has to be handled with care; while a correlation of zero for multivariate normally distributed rvs implies independence, a correlation of zero for, say, t -distributed rvs does *not* imply independence (compare the following paragraph on correlation pitfalls). More general measures of dependence help to avoid these pitfalls. Examples of more general measures for dependence are rank correlation, the coefficient of tail dependence, and association (see **Copulas: Estimation**).

Hence, approaches relying on multivariate Brownian motions and transformations thereof naturally determine the dependence structure *via* correlation. Extending this, there are a number of approaches generalizing the simple linear correlation to a time-varying and stochastic concept (see [3, 8] and references therein).

For two random variables X and Y with finite and positive variances, their *correlation* is defined as

$$\text{Corr}(X, Y) = \frac{\text{Cov}(X, Y)}{\sqrt{\text{Var}(X) \cdot \text{Var}(Y)}} \quad (1)$$

where

$$\text{Cov}(X, Y) = \mathbb{E}[(X - \mathbb{E}(X))(Y - \mathbb{E}(Y))] \quad (2)$$

is the *covariance* of X and Y . We state some properties of correlation: $\text{Corr}(X, Y)$ is a number in $[-1, 1]$ and it is equal to 1 or -1 if and only if X and Y are linearly related, that is, $Y = a + bX$ for constants a, b with $b \neq 0$. The correlation is -1 if $b < 0$ and 1 if $b > 0$. For constants a, b

$$\text{Corr}(X + a, Y + b) = \text{Corr}(X, Y) \quad (3)$$

If X and Y are independent, then $\text{Corr}(X, Y) = 0$. On the other hand, if $\text{Corr}(X, Y) = 0$, X and Y are called *uncorrelated*. In the case when (X, Y) has a bivariate normal distribution, this implies independence of X and Y . Otherwise, this implication is typically wrong: even when X and Y are normally distributed (but (X, Y) does not have a bivariate normal distribution—compare copulas and dependence measurement for an exposition how this may be achieved using copulas), $\text{Corr}(X, Y) = 0$ does not imply independence.

For two random variables belonging to a given class of elliptical distributions,^a which includes the normal distribution and the Student t -distribution, correlation fully determines the dependence structure. However, note that uncorrelated t -distributed random variables are *not* independent.

If X is m -dimensional and Y n -dimensional, then $\text{Cov}(X, Y)$ is given by the $m \times n$ -matrix with entries $\text{Cov}(X_i, Y_j)$. $\Sigma = \text{Cov}(X, X)$ is called *covariance matrix*. Σ is symmetric and positive semidefinite, that is, $x^\top \Sigma x \geq 0$ for all $x \in \mathbb{R}^m$. Moreover, one has

$$\text{Cov}(\mathbf{a} + BX, \mathbf{c} + DY) = B \text{Cov}(X, Y) D^\top \quad (4)$$

for $\mathbf{a} \in \mathbb{R}^o$, $\mathbf{c} \in \mathbb{R}^p$, $B \in \mathbb{R}^{o \times m}$, $D \in \mathbb{R}^{p \times n}$. Similarly, $\text{Corr}(X, Y)$ has the entries $\text{Corr}(X_i, Y_j)$, $1 \leq i \leq m, 1 \leq j \leq n$. The *correlation matrix* of X is $\text{Corr}(X, X)$. It is again symmetric and positive semidefinite. Correlation is invariant under linear increasing transformations such that

$$\text{Corr}(a + bX, c + dY) = \text{Corr}(X, Y) \quad (5)$$

if $bc > 0$. If $bc < 0$ only the sign of the correlation changes.

Correlation Pitfalls

When correlation is used as a measure of dependence a number of pitfalls arise; compare [7] or [13], Chapter 5.2.1 for a detailed exposition. In the following,

we list the typical pitfalls and give a hint why difficulties may arise when linear correlation is used.

1. *A correlation of 0 is not equivalent to independence.* For (X, Y) being jointly normal, $\text{Corr}(X, Y) = 0$ implies independency of X and Y . In general this is not true; even perfectly related rvs can have zero correlation: consider $X \sim \mathcal{N}(0, 1)$ and $Y = X^2$. Then $\text{Corr}(X, Y) = 0$ and X and Y are clearly not independent.
2. *Correlation is invariant under linear transformations, but not under general transformations.* For example, two lognormal rvs have a different correlation than the underlying normal rvs; compare Example 5.26 in [13].
3. *For given distributions of X and Y and some given correlation in $[-1, 1]$ it is, in general, not possible to construct a joint distribution.* For example, if X and Y are lognormally distributed, the interval of attainable correlations is a strict subset of $[-1, 1]$ and becomes smaller with increasing volatility; compare again Example 5.26 in [13].
4. *A small correlation does not imply a small degree of dependency.* This is, in particular, implied by observation 3, and so it is, in general, wrong to deduce a small degree of dependency from a small correlation.

Stylized Facts

Asset correlation shows two typical stylized features:^b

1. *Correlation clustering:* periods of high (low) correlation are likely to be followed by periods of high (low) correlation.
2. *Asymmetry and comovement with volatility:* high volatility in falling markets goes hand in hand with a strong increase in correlation, but this is not the case for rising markets; see [12] or [1].

In [15] the 1987 crash is analyzed and correlation risk is identified as a reason of simultaneous stock-market declines and volatility increases. Notably, this reduces opportunities for diversification in stock-market declines.

Estimating Correlation

The estimation of correlation in financial data is a delicate task as the underlying distribution typically has heavy tails. If this is the case, it is preferable to use robust methods in comparison to nonrobust methods like the sample correlation. Evidence of the efficiency of robust methods like Kendall's rank correlation coefficient is provided in [13], Section 3.3.4. Acknowledging that correlation changes over time, a number of approaches for dynamic correlation have been developed; see, for example, [3, 8] and references therein.

Correlation Risk

Correlation risk refers to the risk of a financial loss when correlation in the market changes. It plays a central role in risk management and the pricing of basket derivatives.

Risk Management

In risk management, correlation risk refers to the risk of a loss in a financial position occurring due to a difference between anticipated correlation and realized correlation. In particular, this occurs when the estimate of correlation was wrong or the correlation in the market changed.

The risk management of a portfolio as well as portfolio optimization heavily depends on the used correlation. This is illustrated by the following simple example: assume that a financial position is given by portfolio weights $w_1, \dots, w_d$ and the distribution of the assets X is multivariate normal. Then the profit and loss (P&L) of the position is $\sum_{i=1}^d w_i X_i$, and is hence normally distributed with mean $\sum_{i=1}^d w_i E(X_i)$ and variance

$$\sum_{i,j=1}^d w_i w_j \text{Cov}(X_i, X_j) \quad (6)$$

which equals $\sum_{i=1}^d w_i^2 \text{Var}(X_i)$ if the positions are uncorrelated. Otherwise, the Value at Risk depends on the correlations of all assets and therefore a change in the correlation may significantly alter the risk of the position.

In the elliptical world, the use of coherent risk measures is related to the Markowitz approach where

the variance is used as a risk measure; see [13], Section 6.1.5. The effects of stochastic correlation on hedging strategies have also been considered in [9]. Section 5 therein also gives some examples on stochastic correlation.

Basket Derivatives

If the pricing of basket derivatives (*see Foreign Exchange Basket Options; Basket Options*) is considered, the value of the derivative itself depends on the (unknown) correlation. In this case, correlation risk refers to the change in the value of the derivative with changing correlation. Note that in contrast to the first example, already the *value* of the derivative itself depends on the correlation. Options of this kind typically are traded in interest markets, foreign exchange markets, or credit markets, examples being quanto (*see Quanto Options*) options, rainbow options, spread options, or collateralized debt obligations (*see Collateralized Debt Obligations (CDO)*). In particular, in credit markets, the term *default correlation* has been coined and contagion and dependencies play a central role. For more references on the role of default correlation risk in credit risky markets, see [10, 11].

By analyzing prices of options on single names and on market indices, Driessen *et al.* [6] show that correlation risk is priced in the options markets. Practitioners trade priced correlation risk by using short positions in index options and long positions in individual options, which is called *dispersion trading* (*see Dispersion Trading*). A similar position can be taken with a correlation swap (*see Correlation Swap*).

In particular, in credit markets, contagion and dependencies play a central role. For more references on the role of default correlation risk in credit risky markets, see [10, 11].

End Notes

^aCompare [13], Theorem 3.25. Section 3.3 therein gives a short introduction to elliptical distributions.

THORSTEN SCHMIDT

Multivariate Distributions

Financial risk models, whether for market or credit risks, are inherently multivariate. For instance, the value change of a portfolio of traded instruments over a fixed time horizon depends on a random vector of risk-factor changes or returns; similarly, the loss incurred by a credit portfolio depends on a random vector of losses for the individual counterparties in the portfolio. In this article, we review some multivariate distributions (models for the distribution of random vectors) that are particularly useful for financial data. Our discussion is based mainly on Chapter 3 of [5]; the closely related issue of copulas and dependence measurement is discussed in **Copulas: Estimation**.

Random Vectors and Their Distributions

In this section, we briefly review some key notions from multivariate statistics.

Joint and Marginal Distributions

Consider a general d -dimensional random vector (think of risk-factor changes or log-returns) $\mathbf{X} = (X_1, \dots, X_d)'$. The dependence between the components of $\mathbf{X}$ is completely described by the *joint distribution function* (df)

$$\begin{aligned} F_{\mathbf{X}}(\mathbf{x}) &= F_{\mathbf{X}}(x_1, \dots, x_d) = P(\mathbf{X} \leq \mathbf{x}) \\ &= P(X_1 \leq x_1, \dots, X_d \leq x_d) \end{aligned} \quad (1)$$

The *marginal* distribution function of X_i , written as F_{X_i} or often simply as F_i , is the df of that risk factor considered individually and is easily calculated from the joint df via

$$\begin{aligned} F_i(x_i) &= P(X_i \leq x_i) \\ &= F(\infty, \dots, \infty, x_i, \infty, \dots, \infty) \end{aligned} \quad (2)$$

where the last expression is understood as the limit, as the respective arguments tend to the upper boundaries of the support of the distribution. If the marginal df $F_i(x)$ is absolutely continuous, then we refer to its derivative $f_i(x)$ as the *marginal density* of X_i . The

df of a random vector $\mathbf{X}$ is said to be *absolutely continuous* if

$$\begin{aligned} F(x_1, \dots, x_d) \\ = \int_{-\infty}^{x_1} \cdots \int_{-\infty}^{x_d} f(u_1, \dots, u_d) du_1 \dots du_d \end{aligned} \quad (3)$$

for some nonnegative function f integrating to one, known as the *joint density* of $\mathbf{X}$.

Conditional Distributions and Independence

If we have a multivariate model for risks in the form of a joint df or density, we can make conditional probability statements about the probability that certain components take certain values given that other components take other values. More precisely, partition $\mathbf{X}$ into $(\mathbf{X}'_1, \mathbf{X}'_2)'$, where $\mathbf{X}_1 = (X_1, \dots, X_k)'$ and $\mathbf{X}_2 = (X_{k+1}, \dots, X_d)'$. Assume that $\mathbf{X}$ is absolutely continuous with density f and denote by $f_{\mathbf{X}_1}(\mathbf{x}_1) = \int f(\mathbf{x}_1, \mathbf{x}_2) d\mathbf{x}_2$ the density of $\mathbf{x}_1$. Then the conditional distribution of $\mathbf{X}_2$ given $\mathbf{X}_1 = \mathbf{x}_1$ has density

$$f_{\mathbf{X}_2|\mathbf{X}_1}(\mathbf{x}_2 | \mathbf{x}_1) = \frac{f(\mathbf{x}_1, \mathbf{x}_2)}{f_{\mathbf{X}_1}(\mathbf{x}_1)} \quad (4)$$

The components of $\mathbf{X}$ are called *mutually independent*, if and only if $F(\mathbf{x}) = \prod_{i=1}^d F_i(x_i)$ for all $\mathbf{x} \in \mathbb{R}^d$ or, in the case where $\mathbf{X}$ possesses a density, $f(\mathbf{x}) = \prod_{i=1}^d f_i(x_i)$.

Moments and Characteristic Function

The *mean vector* of $\mathbf{X}$, when it exists, is given by $E(\mathbf{X}) := (E(X_1), \dots, E(X_d))'$; the *covariance matrix*, when it exists, is the matrix $\Sigma = \text{cov}(\mathbf{X})$ with (i, j) th element given by $\sigma_{ij} = \text{cov}(X_i, X_j) = E(X_i X_j) - E(X_i)E(X_j)$, the ordinary pairwise covariance between X_i and X_j . The diagonal elements $\sigma_{11}, \dots, \sigma_{dd}$ are the variances of the components of $\mathbf{X}$. Mean vectors and covariance matrices are extremely, easily manipulated under linear operations on the vector $\mathbf{X}$. For any matrix $B \in \mathbb{R}^{k \times d}$ and vector $\mathbf{b} \in \mathbb{R}^k$, we have

$$E(B\mathbf{X} + \mathbf{b}) = BE(\mathbf{X}) + \mathbf{b} \quad (5)$$

$$\text{cov}(B\mathbf{X} + \mathbf{b}) = B \text{cov}(\mathbf{X}) B' \quad (6)$$

Covariance matrices are symmetric and positive semidefinite. In case that Σ is positive definite ($\mathbf{a}'\Sigma\mathbf{a} > 0$ for any $\mathbf{a} \in \mathbb{R}^d \setminus \{0\}$), we can use the well-known *Cholesky factorization* $\Sigma = AA'$ for a lower triangular matrix A with positive diagonal elements known as the *Cholesky factor*; this decomposition is very useful for simulation purposes.

An important tool for studying multivariate distributions is the *characteristic function* of a random vector (or its distribution), given by

$$\phi_{\mathbf{X}}(\mathbf{t}) = E\left(e^{i\mathbf{t}'\mathbf{X}}\right), \quad \mathbf{t} \in \mathbb{R}^d \quad (7)$$

The Multivariate Normal Distribution

The multivariate normal distribution is central to much of classical multivariate analysis and provided the starting point for attempts to model market risk via the variance–covariance method (see **Market Risk** or Chapter 2 of [5]); moreover, it is an important building block for constructing more refined distributions.

Definition and Basic Properties

A random vector $\mathbf{X} = (X_1, \dots, X_d)'$ has a *multivariate normal* or *Gaussian* distribution if

$$\mathbf{X} \stackrel{d}{=} \boldsymbol{\mu} + A\mathbf{Z} \quad (8)$$

where $\mathbf{Z} = (Z_1, \dots, Z_k)'$ is a vector of independent and identically distributed (iid) univariate *standard* normal random variables (rvs) (mean zero and variance one), and $A \in \mathbb{R}^{d \times k}$ and $\boldsymbol{\mu} \in \mathbb{R}^d$ are the matrix and vector of constants, respectively. It is easy to verify, using equations (5) and (6), that the mean vector of this distribution is $E(\mathbf{X}) = \boldsymbol{\mu}$ and the covariance matrix is $\text{cov}(\mathbf{X}) = \Sigma$, where $\Sigma = AA'$ is a positive semidefinite matrix. Moreover, using the fact that the characteristic function of a standard univariate normal variate Z is $\phi_Z(t) = \exp(-t^2/2)$, the characteristic function of $\mathbf{X}$ may be calculated to be

$$\phi_{\mathbf{X}}(\mathbf{t}) = E\left(e^{i\mathbf{t}'\mathbf{X}}\right) = \exp\left(i\mathbf{t}'\boldsymbol{\mu} - \frac{1}{2}\mathbf{t}'\Sigma\mathbf{t}\right), \quad \mathbf{t} \in \mathbb{R}^d \quad (9)$$

Clearly, the distribution is characterized by its mean vector and covariance matrix, and hence a standard

notation is $\mathbf{X} \sim N_d(\boldsymbol{\mu}, \Sigma)$. Note that the components of $\mathbf{X}$ are mutually independent if and only if Σ is diagonal. For example, $\mathbf{X} \sim N_d(\mathbf{0}, I_d)$ if and only if $X_1, \dots, X_d$ are iid $N(0, 1)$, the standard univariate normal distribution.

We concentrate on the *nonsingular* case of the multivariate normal when $\text{rank}(A) = d \leq k$. In this case, the covariance matrix Σ has full rank d and is therefore invertible (nonsingular) and positive definite. Moreover, $\mathbf{X}$ has an absolutely continuous distribution function with joint density given by

$$f(\mathbf{x}) = \frac{1}{(2\pi)^{\frac{d}{2}} |\Sigma|^{\frac{1}{2}}} \times \exp\left\{-\frac{(\mathbf{x} - \boldsymbol{\mu})'\Sigma^{-1}(\mathbf{x} - \boldsymbol{\mu})}{2}\right\}, \quad \mathbf{x} \in \mathbb{R}^d \quad (10)$$

where $|\Sigma|$ denotes the determinant of Σ . In the singular case, the support of the distribution of $\mathbf{X}$ is a strict subspace of $\mathbb{R}^d$ and a joint density does not exist. The form of the density clearly shows that points with equal density lie on *ellipsoids* determined by equations of the form $(\mathbf{x} - \boldsymbol{\mu})'\Sigma^{-1}(\mathbf{x} - \boldsymbol{\mu}) = c$, for constants $c > 0$.

In order to generate a realization $\mathbf{X} \sim N_d(\boldsymbol{\mu}, \Sigma)$ with Σ positive definite, one would proceed as follows:

1. Perform a Cholesky decomposition $\Sigma = AA'$ of the covariance matrix Σ (see, e.g., [6]).
2. Generate a vector $\mathbf{Z} = (Z_1, \dots, Z_d)'$ of independent standard normal variates and set $\mathbf{X} = \boldsymbol{\mu} + A\mathbf{Z}$.

We now summarize further useful properties of the multivariate normal that underline the attractiveness of this distribution for computational work in risk management. *Linear combinations* of multivariate normal random vectors are multivariate normal; if $\mathbf{X} \sim N_d(\boldsymbol{\mu}, \Sigma)$, we have for any $B \in \mathbb{R}^{k \times d}$ and $\mathbf{b} \in \mathbb{R}^k$ that

$$B\mathbf{X} + \mathbf{b} \sim N_k(B\boldsymbol{\mu} + \mathbf{b}, B\Sigma B') \quad (11)$$

As a special case, if $\mathbf{a} \in \mathbb{R}^d$, then $\mathbf{a}'\mathbf{X} \sim N(\mathbf{a}'\boldsymbol{\mu}, \mathbf{a}'\Sigma\mathbf{a})$, and this fact is used routinely in the variance–covariance approach to risk management. Similarly, marginal distributions of a multivariate normal random vector are univariate normal.

Assuming Σ is positive definite, the *conditional distributions* of $\mathbf{X}_2$ given $\mathbf{X}_1$ and of $\mathbf{X}_1$ given $\mathbf{X}_2$ may also be shown to be multivariate normal. For example, $\mathbf{X}_2 | \mathbf{X}_1 = \mathbf{x}_1 \sim N_{d-k}(\boldsymbol{\mu}_{2.1}, \Sigma_{22.1})$ where

$$\begin{aligned}\boldsymbol{\mu}_{2.1} &= \boldsymbol{\mu}_2 + \Sigma_{21} \Sigma_{11}^{-1} (\mathbf{x}_1 - \boldsymbol{\mu}_1) \quad \text{and} \\ \Sigma_{22.1} &= \Sigma_{22} - \Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12}\end{aligned}\quad (12)$$

are the conditional mean vector and covariance matrix.

Multivariate Normal Distributions as Model for Asset Returns

There are numerous empirical tests of the suitability of the multivariate normal distribution as a model for log-returns (risk-factor changes) for financial data. These tests involve both testing the hypothesis that marginal log-returns are normal (univariate tests) and tests for multivariate normality; details and further references can, for instance, be found in Section 3.1.4 of [3]. Broadly speaking, the outcome of these tests points to three main defects of the multivariate normal distribution (at least for data over a shorter time horizon such as daily or even monthly data):

1. The tails of its univariate marginal distributions are too thin; they do not assign enough weight to *extreme* events.
2. The joint tails of the distribution do not assign enough weight to *joint extreme* outcomes.
3. The distribution has a strong form of symmetry known as *elliptical symmetry*.

In the next section, we look at models that address some of these defects.

Variance Mixtures and Elliptical Distributions

Normal Mixture Distributions

The random vector $\mathbf{X}$ is said to have a *multivariate normal variance mixture distribution* if

$$\mathbf{X} \stackrel{d}{=} \boldsymbol{\mu} + \sqrt{W} \mathbf{A} \mathbf{Z} \quad \text{where} \quad (13)$$

$\mathbf{Z} \sim N_k(\mathbf{0}, \mathbf{I}_k)$; $\mathbf{A} \in \mathbb{R}^{d \times k}$ and $\boldsymbol{\mu} \in \mathbb{R}^d$ are a matrix, respectively, a vector of constants; and where $W \geq 0$

is a nonnegative, scalar-valued rv, which is independent of $\mathbf{Z}$. Such distributions are known as *variance mixtures*, since $\mathbf{X} | W = w \sim N_d(\boldsymbol{\mu}, w \Sigma)$ where $\Sigma = \mathbf{A} \mathbf{A}'$. The distribution of $\mathbf{X}$ can be considered as a composite distribution, constructed by taking a set of multivariate normal distributions with the same mean vector and with the same covariance matrix up to a multiplicative constant w ; the mixture distribution—which is generally not a normal distribution—is then constructed by drawing randomly from this set of component multivariate normals according to a set of “weights” determined by the distribution of W .

Provided W has a finite expectation, we may easily calculate that $E(\mathbf{X}) = \boldsymbol{\mu}$ and that $\text{cov}(\mathbf{X}) = E(W) \Sigma$. Note that normal variance mixtures provide nice examples of models where a lack of correlation does not necessarily imply independence of the components of $\mathbf{X}$; indeed, it can be shown that two uncorrelated rvs (X_1, X_2) having a normal mixture distribution with $E(W) < \infty$ are independent, if and only if W is almost surely constant, that is, if (X_1, X_2) are bivariate normally distributed.

The *characteristic function* of a multivariate normal variance mixture is given by

$$\phi_{\mathbf{X}}(\mathbf{t}) = \exp(i \mathbf{t}' \boldsymbol{\mu}) \widehat{H}(\mathbf{t}' \Sigma \mathbf{t} / 2) \quad (14)$$

where $\widehat{H}(\theta) = \int_0^\infty e^{-\theta v} dH(v)$ is the Laplace–Stieltjes transform of the df H of W . We use the notation $\mathbf{X} \sim M_d(\boldsymbol{\mu}, \Sigma, \widehat{H})$ for normal variance mixtures. Assuming that Σ is positive definite and that the distribution of W places no point mass at zero, the density of $\mathbf{X} \sim M_d(\boldsymbol{\mu}, \Sigma, \widehat{H})$ becomes

$$\begin{aligned}f(\mathbf{x}) &= \int \frac{w^{-\frac{d}{2}}}{(2\pi)^{\frac{d}{2}} |\Sigma|^{\frac{1}{2}}} \\ &\times \exp \left\{ -\frac{(\mathbf{x} - \boldsymbol{\mu})' \Sigma^{-1} (\mathbf{x} - \boldsymbol{\mu})}{2w} \right\} dH(w)\end{aligned}\quad (15)$$

Note that all such densities depend on $\mathbf{x}$ only through the quadratic form $(\mathbf{x} - \boldsymbol{\mu})' \Sigma^{-1} (\mathbf{x} - \boldsymbol{\mu})$.

The most important example is provided by the *multivariate t -distribution*. Here, we take W in equation (13) to be a rv with an inverse gamma distribution $W \sim \text{Ig}(\nu/2, \nu/2)$ (which is equivalent to

saying that $\nu/W \sim \chi_\nu^2$). The notation for this distribution is $\mathbf{X} \sim t_d(\nu, \boldsymbol{\mu}, \Sigma)$. Since $E(W) = \nu/(\nu - 2)$, we have $\text{cov}(\mathbf{X}) = \frac{\nu}{\nu - 2} \Sigma$ and the covariance matrix of this distribution is only defined if $\nu > 2$. Using equation (15), the density can be calculated to be

$$f(\mathbf{x}) = \frac{\Gamma\left(\frac{\nu + d}{2}\right)}{\Gamma\left(\frac{\nu}{2}\right) (\pi\nu)^{\frac{d}{2}} |\Sigma|^{\frac{1}{2}}} \times \left(1 + \frac{(\mathbf{x} - \boldsymbol{\mu})' \Sigma^{-1} (\mathbf{x} - \boldsymbol{\mu})}{\nu}\right)^{-\frac{\nu+d}{2}} \quad (16)$$

The multivariate t has heavier marginal tails than the normal distribution and a more pronounced tendency to generate simultaneous extreme outcomes (see also **Copulas: Estimation**).

Normal variance mixture distributions are easy to work with under linear operations; if $\mathbf{X} \sim M_d(\boldsymbol{\mu}, \Sigma, \hat{H})$ and $\mathbf{Y} = B\mathbf{X} + \mathbf{b}$ where $B \in \mathbb{R}^{k \times d}$ and $\mathbf{b} \in \mathbb{R}^k$, then $\mathbf{Y} \sim M_k(B\boldsymbol{\mu} + \mathbf{b}, B\Sigma B', \hat{H})$. Thus, linear transformations of $\mathbf{X}$ remain in the subclass of mixture distributions specified by $\hat{H}$ or, equivalently, by the mixing variable W of which $\hat{H}$ is the Laplace–Stieltjes transform. For example, if $\mathbf{X}$ has a multivariate t distribution with ν degrees of freedom, then so does any linear transformation of $\mathbf{X}$.

Normal Mean–variance Mixture Distributions

The definition (13) can be generalized to allow for skewed distributions: $\mathbf{X}$ is said to have a multivariate normal mean–variance mixture distribution if

$$\mathbf{X} \stackrel{d}{=} \boldsymbol{\mu} + W\boldsymbol{\gamma} + \sqrt{W}A\mathbf{Z} \quad (17)$$

For instance, if we assume $W \sim N^-(\lambda, \chi, \psi)$ (a generalized inverse Gaussian distribution), we obtain the class of (multivariate) *generalized hyperbolic distributions* (see **Generalized Hyperbolic Models**). These distributions have important applications in finance and risk management; in particular, they are infinitely divisible and therefore directly connected to *Lévy processes* (see **Lévy Processes**). Note that mean–variance mixture distributions are, in general, skewed; in particular, the density is no longer constant on ellipsoids. We refer to Section 3.2.4 of [5] for further information and further references about this class.

Spherical and Elliptical Distributions

Many important distribution have densities that are constant on ellipsoids and thus belong to the class of *elliptical distributions*; this class has some theoretical properties that makes it attractive as a model for the joint distribution of risk factors. Elliptical distributions are defined as affine transformations of *spherical* random vectors. A random vector $\mathbf{X} = (X_1, \dots, X_d)'$ has a spherical distribution, if, for every orthogonal map $U \in \mathbb{R}^{d \times d}$ (i.e., maps satisfying $UU' = U'U = I$), one has $U\mathbf{X} \stackrel{d}{=} \mathbf{X}$. Spherical random vectors are thus distributionally invariant under rotations. It can be shown that $\mathbf{X}$ is spherical if and only if one of the following properties hold:

1. There exists a function ψ of a scalar variable, called *characteristic generator*, such that, for all $\mathbf{t} \in \mathbb{R}^d$,

$$\phi_{\mathbf{X}}(\mathbf{t}) = E\left(e^{i\mathbf{t}'\mathbf{X}}\right) = \psi(\mathbf{t}'\mathbf{t}) = \psi(t_1^2 + \dots + t_d^2) \quad (18)$$

2. For every $\mathbf{a} \in \mathbb{R}^d$, one has $\mathbf{a}'\mathbf{X} \stackrel{d}{=} \|\mathbf{a}\|X_1$, where $\|\mathbf{a}\|^2 = \mathbf{a}'\mathbf{a} = a_1^2 + \dots + a_d^2$.
 $\mathbf{X}$ has an *elliptical distribution* if

$$\mathbf{X} \stackrel{d}{=} \boldsymbol{\mu} + A\mathbf{Y} \quad (19)$$

where $\mathbf{Y}$ is spherical and $A \in \mathbb{R}^{d \times k}$ and $\boldsymbol{\mu} \in \mathbb{R}^d$ are a matrix and vector of constants, respectively. The characteristic function can be written as $\phi_{\mathbf{X}}(\mathbf{t}) = e^{i\mathbf{t}'\boldsymbol{\mu}} \psi(\mathbf{t}'A\mathbf{t})$, where $\psi(\cdot)$ is the characteristic generator of $\mathbf{Y}$ introduced in equation (18). Examples include the multivariate normal distribution and, more generally, the multivariate variance mixture distributions (13). Elliptical distributions share many properties with the multivariate normal distribution: affine transformations of elliptical random vectors and, in particular, marginal distributions remain elliptical with the same generator ψ ; if we condition on one or several components of an elliptical random vector, the ensuing conditional distribution is elliptical, albeit, in general, with a different generator.

An important property of elliptical distributions for risk management purposes is the fact that Value at Risk (VaR) (see **Value-at-Risk**) is a *coherent risk measure* (see **Convex Risk Measures**) if restricted to the set of all linear combinations of the components of some elliptical random vector.

Notes and Further References

Much of the material from the sections “Random Vectors and Their Distributions” and “The Multivariate Normal Distribution” can be found in greater detail in standard texts on multivariate statistical analysis such as [4, 7]. There are countless possible tests of univariate normality and a good starting point is the entry on *Departures from Normality, Tests for* in volume 2 of the Encyclopedia of Statistics [3]; the latter source also contains tests for multivariate normality.

A comprehensive reference for the spherical and elliptical distributions (including a special treatment of symmetric variance mixture models) is given by Fang *et al.* [2]. A useful reference on the multivariate generalized hyperbolic distribution is Blæsild [1].

Electricity Markets

Since the early 1990s, an increasing number of countries worldwide have liberalized their electricity power sectors. Contrary to the situation that prevailed earlier, when power sectors were not open to competition and prices were set by regulators according to the cost of generation, transmission, and distribution, electricity prices are now determined by an equilibrium of supply and demand, which introduces a substantial price risk with volatilities much higher than those of equity prices. A big share of the total electricity in liberalized power markets is traded over the counter through bilateral agreements. There exists a rich variety of exotic options traded in this market. On the other hand, similar to how the end of the Bretton Woods system in 1973 caused the appearance of currency exchanges, the deregulation of electricity markets has led to the creation of organized electricity exchanges, where electricity is quoted almost as any other commodity (see Table 1 for a list of the major European electricity exchanges).

Although commonly referred to as *commodity*, electricity is in many ways different from the more classical commodities like oil, coal, metals, and agriculture. One substantial difference is that electricity has very limited storage possibilities. To a certain degree, producers may store electricity indirectly in water reservoirs (for hydro-based electricity production) or *via* gas, oil, or coal (for thermal electricity production). However, the consumer of electricity cannot buy for storage. This implies that electricity is not a tradable asset (in the sense that one can buy the asset and sell it later on), and usual hedging arguments to price futures/forwards and other derivatives cannot be applied. Other effects of the lack of storability are strong seasonal and very volatile price behavior. Also, because electricity is only useful when sourced continuously in time, all power contracts concern the delivery of electricity over a *period* of time and not at a fixed point in time. In this sense, electricity markets share more similarities with temperature and also natural gas markets than with the more classical commodity markets. Like electricity, both temperature and natural gas exhibit restricted storage possibilities (storage is impossible for temperature and rather costly for gas), and the corresponding traded contracts are of *flow-over-a-period* type.

Contracts traded on electricity exchanges can typically be divided into two categories: contracts with physical delivery and financially settled contracts. In the following, we shortly sketch the organization of the Scandinavian exchange Nord Pool, but the situation is similar at most other electricity exchanges.

Contracts with physical delivery include actual consumption or production of electricity as part of contract fulfillment. The market for physical delivery is supervised by a so-called transmission system operator (TSO) who balances supply and demand, and market participants are those with proper facilities for production or consumption. Further, contracts with physical delivery are organized in two different submarkets: the *real-time* and the *day-ahead* markets, known as the *two-settlement system*. On the day-ahead market, hourly power contracts for the next day's 24 h (midnight to midnight) are traded. Each day at noon, the day-ahead market is closed for bids and prices for each hour the next day are derived. Electricity prices on the day-ahead market are referred to as *spot prices* as they are reference prices for the financially settled futures/forward contracts. The real-time market, on the other hand, is organized for short-term upward or downward regulation and bids may be posted or changed close to operational time. In both the day-ahead and the real-time market, prices are derived in auctions. The TSO lists bids for each hour according to the price, the so-called *merit order*, and prices are derived by balancing supply and demand.

Financial power contracts are settled financially against a reference price. The market for financial electricity contracts does not require central coordination but can be considered as side bets on the physical system. In contrast to the physical market, a big share of the market players are speculators. The predominantly traded financial contracts are futures/forward type contracts written on the (weighted) average of the hourly spot price (day-ahead market) over a specific *delivery period*. At Nord Pool, there exist daily and weekly contracts of futures type with margin accounts, and monthly, quarterly, and yearly contracts of forward type. Besides futures/forwards contracts, Nord Pool's financial market also organizes trade in European call and put options written on futures/forwards, however, in much smaller volumes.

The substantial electricity price risk introduced by the liberalization of electricity markets requires a precise statistical modeling for risk management,

Table 1 Major European electricity exchanges

Country	Starting date	Name
England and Wales	1990	Electricity pool
Scandinavia	2001	UK Power Exchange (UKPX)
	1993	Nord Pool (Norway only)
	From 1996	Sweden, Denmark, Finland consecutively joined Nord Pool
Spain	1998	OMEL
Netherlands	1999	Amsterdam Power Exchange (APX)
Germany	2000	Leipzig Power Exchange (LPX)
	2001	European Power Exchange (EEX)
Poland	2000	Polish Power Exchange
France	2001	Powernext
Italy	2004	Gestore Mercato Elettrico (GME)

pricing, and asset evaluation purposes. Over recent years, a number of models have been proposed, which basically can be separated in two categories. Models in the first category aim at directly modeling the dynamics of the complete electricity futures curve and, to this end, techniques known from interest rate modeling have been transferred to electricity futures curve modeling (see e.g., [4, 5, 16, 17], and the book [6] with references therein). One of the main problems with this approach is that electricity futures curves seem to have far more complex dynamics than interest rate curves. It seems hardly possible to model the complete futures curve including the spot price in the short end with a reasonable number of factors.

Models in the second category aim at modeling the dynamics of the spot price of electricity. In this framework, the main difficulty when it comes to futures/forwards and other derivatives pricing is the nonstorability of electricity, which makes the market highly incomplete. The cost-of-carry relationship between spot and forward prices breaks down, and a pricing measure (equivalently, market price of risk) has to be identified. Also, since forward-looking information on a nonstorable asset is not reflected by actual price behavior of this asset, one has to be cautious about the market information modeling [7].

In the following text, we consider reduced-form electricity spot price models, which are members of the second category. In particular, in the section Stylized Feature of Electricity Spot Prices we present the stylized features of electricity spot prices to take into account when specifying a model, before we give a review of reduced-form spot models existing in

the literature in the section Reduced-form Electricity Spot Price Models.

Stylized Feature of Electricity Spot Prices

In Figure 1, a section of the daily Nord Pool spot price is shown, which behaves very nicely in the sense that it illustrates well the qualitative characteristics to take into account when specifying a spot price model. In [23], a systematic statistical analysis is performed on spot data from seven electricity exchanges (two American and five European) and the following list of five stylized features common to all data sets has been identified.

- **Seasonality**
Electricity spot prices reveal seasonal behavior in yearly, weekly, and daily cycles. However, the seasonality has little effect on the overall variability of the price data.
- **Stationarity**
Similar to other commodities, electricity prices tend to exhibit stationary behavior. They are mean reverting to a trend which, however, may exhibit slow stochastic variations (see Figure 2).
- **Multiscale autocorrelation**
The observed autocorrelation structure of most European price series is described quite precisely with a weighted sum of exponentials:

$$\sum_{i=1}^n w_i e^{-h\lambda_i} \quad (1)$$

where the number n of factors needed for a good description is 2 or 3, and the weights w_i add

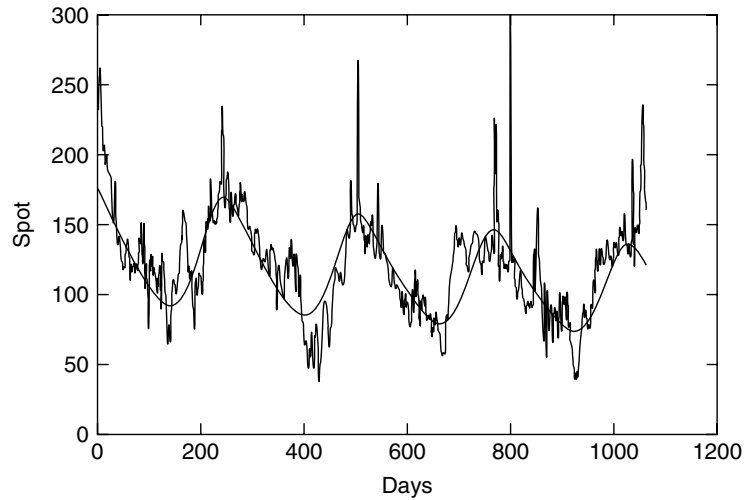

Figure 1 Daily spot price at Nord Pool spanning the period April 1, 1997–July 14, 2000

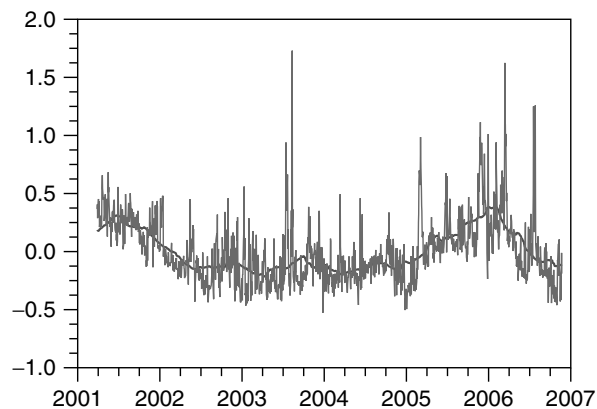

Figure 2 UKPX time series (after the seasonality has been removed) and its 6-month moving average

up to 1 (see Figure 3). We mention that the two American and also the Nord Pool price series exhibit a quite different, almost nonstationary, autocorrelation structure, which might be due to different market organization.

- **Spikes**

All data sets of electricity spot prices show impressive spikes, that is, violent upward jumps followed by rapid return to about the same level. The intensity of spike occurrence can vary over time. This fundamental property of electricity prices is due to the nonstorability

of this commodity, and any relevant spot price model must take this feature into account. In [19, 23], it is ascertained that appropriate modeling of spike risk requires a Pareto-like distribution with polynomial tail.

- **Non-Gaussianity**

The examination of daily spot prices reveals a highly non-Gaussian distribution, which tends to be slightly positively skewed and strongly leptokurtic. This high excess kurtosis is explained by the presence of the low-probability large-amplitude spikes.

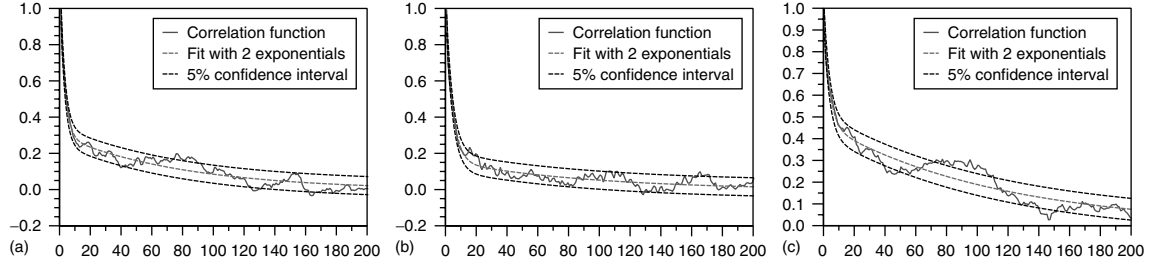

Figure 3 Fitting the autocorrelation function with a sum of two exponentials. (a–c) APX, EEX, UKPX

Reduced-form Electricity Spot Price Models

We conclude this article by presenting some spot price models existing in the literature. For this, we restrict to an overview as given in [23] of *reduced-form models* in continuous time, but we mention that there is a variety of different spot model types like *hybrid models* or *econometric time series models* (see, e.g., [20, 21, 24] or the text books [9, 12, 13, 26] with references therein).

Structural Models

Structural or equilibrium models as proposed in [1, 18] derive prices by balancing supply and demand. The (very inelastic) demand for electricity is described by a stochastic process

$$D_t = \overline{D}_t + X_t \quad (2)$$

$$dX_t = (\mu - \lambda X_t) dt + \sigma dW_t \quad (3)$$

where $\overline{D}_t$ describes the seasonal component and X_t corresponds to the stationary stochastic part. The price is obtained by matching the demand level with a deterministic supply function. In particular, the supply function must be nonlinear and strongly increasing in the right end to account for exploding cost of electricity generation (price spikes) in times of sudden rise in demand. Barlow [1] proposes

$$P_t = \left(\frac{a_0 - D_t}{b_0} \right)^{1/\alpha} \quad (4)$$

for some $\alpha > 0$, while Kanamura and Ohashi [18] suggest a “hockey stick” profile

$$P_t = (a_1 + b_1 D_t) 1_{D_t \leq D_0} + (a_1 + b_1 D_t) 1_{D_t > D_0} \quad (5)$$

Further, we mention in this category market equilibrium models as derived in [8, 15].

Markov Models

Geman and Roncoroni [14] model the electricity log-price as a one-factor Markov jump diffusion.

$$dP_t = \theta(\mu_t - P_t) dt + \sigma dW_t + h(t) dJ_t \quad (6)$$

The spikes are introduced by making the jump direction and intensity level-dependent: if the price is high, the jump intensity is high and downward jumps are more likely, whereas if the price is low, jumps are rare and upward-directed.

Regime-switching Models

In the one-factor Markov specification of Geman and Roncoroni [14], the “spike regime” is distinguished from the “base regime” by a deterministic threshold on the price process: if the price is higher than a given value, the process is in the “spike regime”; otherwise it is in the “base regime”. This threshold value may be difficult to calibrate and it is not very realistic to suppose that it is determined in advance. Regime-switching models as in [27] alleviate this problem by introducing a two-state unobservable Markov chain, which determines the transition from “base regime” to “spike regime” with greater volatility and faster mean reversion:

$$dP_t = \theta^1(\mu_t - P_t) + \sigma^1 dW_t \quad (\text{base regime}) \quad (7)$$

$$dP_t = \theta^2(\mu_t - P_t) + \sigma^2 dW_t \quad (\text{spike regime}) \quad (8)$$

Multifactor Ornstein–Uhlenbeck Models

Multifactor Ornstein–Uhlenbeck models describe the deseasonalized logarithmic spot price (geometric models), alternatively the deseasonalized spot

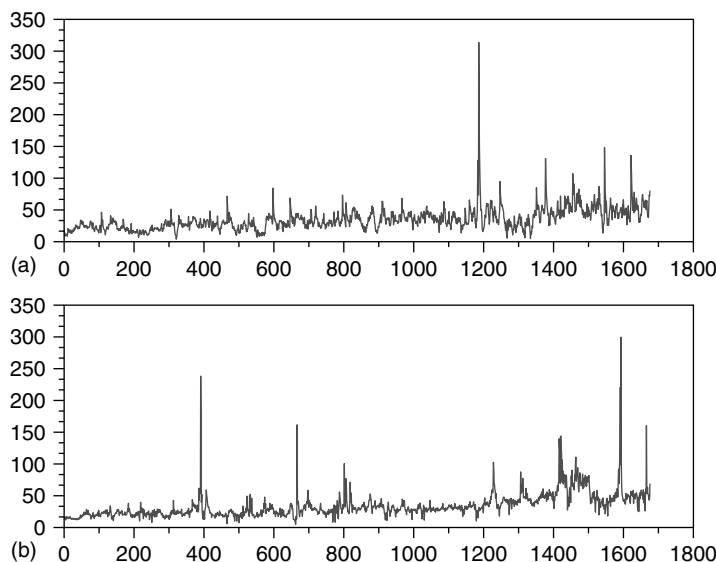

Figure 4 Comparison of the real EEX series (b) and the simulated series with estimated parameters (a)

price (arithmetic models), as a sum of independent Lévy-driven Ornstein–Uhlenbeck components:

$$X(t) = \sum_{i=1}^n Y_i(t) \quad (9)$$

$$dY_i(t) = -\lambda_i Y_i(t) dt + dL_i(t), \quad Y_i(0) = y_i \quad (10)$$

where processes $L_i(t)$ are independent, possibly time inhomogeneous Lévy processes. For example, in the case of a two-factor model, the first factor corresponds to the stochastic base signal with a slow rate of mean reversion λ_1 , and the second factor represents the spikes and has a high rate of mean reversion λ_2 . The earliest model in this family proposed in the literature is a Gaussian one-factor model in [25]. Subsequently, several authors have proposed various improvements [2, 3, 11, 22]. We also mention here the model in [10], which is a mixture of a structural and a multifactor model.

Multifactor Ornstein–Uhlenbeck models are capable of capturing all the stylized features presented in the previous section and to precisely describe daily spot price dynamics. In particular, the arithmetic model proposed in [3] can reproduce the multiscale autocorrelation structure of European spot prices, and, at the same time, it is mathematically very

tractable. However, due to their non-Markovianity, in case of several factors, estimation of multifactor models is not obvious. In [19, 23], we develop statistical estimation procedures based on separation of the data into a spike and a base component. In [23], this procedure is based on methods from nonparametric statistics, while we use tools from extreme value theory in [19]. Figure 4 shows a simulation of a two-factor model as a result of an estimation on EEX data in [19].

Electricity Forward Contracts

In quantitative modeling of the electricity market, a fundamental question is to establish the link between spot and forward prices. The classical theory of arbitrage, including storage and convenience yield, does not easily carry over to electricity because of a single complicating fact: the nonstorability of the commodity. In this article, we discuss the spot-forward relation for electricity in view of the classical theory.

Forward Pricing by No Arbitrage

Let us recall how to derive forward prices using no-arbitrage arguments. Denote by $S(t)$ the spot price of an asset at time $t \geq 0$, and consider a forward contract with delivery at time $T \geq t$. To prevent arbitrage opportunities, the forward price $f(t, T)$ at time t must be

$$f(t, T) = S(t) \exp(r(T - t)) \quad (1)$$

with $r > 0$ being the risk-free interest rate. If this is not the case, we can exploit a buy-and-hold strategy to obtain arbitrage. For example, if $f(t, T) > S(t) \exp(r(T - t))$, finance a purchase of the spot contract with borrowing money and go short the forward. At delivery, hand over the spot, pay the debt with continuously compounding interest r , and receive the forward price. This entails in a sure win $f(t, T) - S(t) \exp(r(T - t))$. Obviously, if the forward price is less than $S(t) \exp(r(T - t))$, the strategy above is reversed. A fundamental assumption in this trading scheme is the storability of the spot.

If $S(t)$ is a *semimartingale process* on a *filtered probability space* $(\Omega, (\mathcal{F}_t), \mathcal{F}, P)$, there exists *risk neutral probabilities* Q such that the discounted spot price is a Q -martingale. The forward price can be represented alternatively as a conditional expectation with respect to Q , that is,

$$f(t, T) = \mathbb{E}_Q[S(T) | \mathcal{F}_t] \quad (2)$$

where $\mathcal{F}_t$ is the given information filtration in the market. We remark in passing that, in general, we have many pricing measures Q for a semimartingale

process, but because of the buy-and-hold strategy we get a unique forward price.

The *risk premium* is defined as the difference between the forward price and the predicted spot price at delivery, that is,

$$P(t, T) \triangleq f(t, T) - \mathbb{E}[S(T) | \mathcal{F}_t] \quad (3)$$

Letting $S(t)$ be a geometric Brownian motion,

$$dS(t) = \mu S(t) dt + \sigma S(t) dB(t) \quad (4)$$

we easily find that

$$P(t, T) = S(t) (e^{r(T-t)} - e^{\mu(T-t)}) \quad (5)$$

which is negative in “normal” markets since the expected return μ is naturally bigger than the risk-free interest rate. Hence, the forward price is below the expected spot, which is referred to as the forward market being in *normal backwardation*. In economical terms, this is explained as the producers wanting to secure their future income and hence creating a hedging pressure in the market. The opposite situation, when the risk premium is positive, is referred to as the forward market being *contango*.

One can easily imagine frictions in the market preventing the feasibility of the buy-and-hold strategy. Typically, in commodity markets, costs related to storage and transportation are incurred. The price for storage leads to a modification of the forward price. One also talks of a *convenience yield* in commodity markets, understanding a discount in the forward price due to the *convenience* to own the underlying spot. In effect, these modifications lead to a forward price

$$f(t, T) = S(t) \exp((r - \delta)(T - t)) \quad (6)$$

where δ is a factor accounting for storage, convenience yield, transportation, and so on.

The forward price can still be expressed in terms of a conditional expectation as in equation (2), but now we use pricing measures Q , which do not necessarily turn the discounted spot dynamics into a Q -martingale. Hence, by a specific choice of Q one may represent equation (6) as in equation (2). Considering the specific case of a geometric Brownian motion again, equation (6) is obtained by using the *Girsanov transformation* to introduce a measure Q under which

$$dW(t) = \frac{\mu - (r - \delta)}{\sigma} dt + dB(t) \quad (7)$$

is a Brownian motion. Note that this change of measure does not turn the discounted spot price into a Q -martingale. However, more importantly, normal backwardation is no longer the immediate implication, since the sign of the risk premium

$$P(t, T) = S(t) (e^{(r-\delta)(T-t)} - e^{\mu(T-t)}) \quad (8)$$

is determined by the relation between r , δ , and μ which is not *a priori* clear. Thus, we may have a market either in contango or in backwardation; however, we cannot have both in the sense that the sign of the risk premium changes with time to maturity of the contracts.

The Case of Electricity

In real electricity markets, the forward and futures contracts^a deliver the power over a period rather than at a specific future time point. Thus, a long position entered at time t in an electricity forward delivering over the period $[\tau_1, \tau_2]$, $t \leq \tau_1$ gives a profit/loss

$$\int_{\tau_1}^{\tau_2} S(T) dT - (\tau_2 - \tau_1) F(t, \tau_1, \tau_2) \quad (9)$$

with $F(t, \tau_1, \tau_2)$ being the forward price denoted in a currency per megawatt hour.^b The question is what $F(t, \tau_1, \tau_2)$ should be.

Electricity is a nonstorable commodity by physical nature. Once purchased, we must use it, and any buy-and-hold strategy is not feasible. One cannot talk of any storage costs for electricity and nor of any convenience yield. This means that there is no natural connection as in equation (6). However, based on equation (2) we can *define* the electricity forward price as

$$F(t, \tau_1, \tau_2) = \mathbb{E}_Q \left[\frac{1}{\tau_2 - \tau_1} \int_{\tau_1}^{\tau_2} S(T) dT \mid \mathcal{F}_t \right] \quad (10)$$

Interchanging expectation and dT -integration, we get

$$F(t, \tau_1, \tau_2) = \frac{1}{\tau_2 - \tau_1} \int_{\tau_1}^{\tau_2} f(t, T) dT \quad (11)$$

indicating that an electricity forward corresponds to the average of forward contracts delivering at each time point t in the settlement period.

In order to make equation (10) or (11) operational, one must specify a spot price dynamics and a pricing

measure Q . Since $S(t)$ is nonstorable, it cannot be used for any hedging purposes, and in this respect functions only like an index for the forward price. We can therefore choose any stochastic dynamics we like for the spot, even going beyond the semimartingale framework as is usually required in mathematical finance. The pricing measure Q is *a priori* any equivalent probability measure. In practice, however, we want to choose a Q such that we know the dynamics of S under this measure to be able to calculate the conditional expectation. A valid choice is $Q = P$; however, this would imply a zero-risk premium, which is hardly a realistic situation.

Empirical investigations in electricity markets show that one may have a change of sign in the risk premium. Thus, it may not be the case that the market is either in normal backwardation or in contango. In fact, one has observed a positive premium in the short end of the forward market, whereas contracts with maturity in the longer end have a negative premium. The latter is consistent with producers creating a hedging pressure since they want to lock in their production. However, the positive premium in the short end has been explained by the consumers' wish to hedge the spike risk inherent in spot prices. Thus, in order to hedge the risk of paying a high spot price, the consumers are willing to pay a premium. See [7] for more on this. Bessembinder and Lemmon [5] develop an equilibrium model for the electricity market with consumers and producers. On the basis of a discrete-time equilibrium model for the spot prices, the authors show that the risk premium in the forward market depends on both price variation and right skewedness of prices. Longstaff and Wang [8] found empirical evidence for these propositions in the Pennsylvania, New Jersey, and Maryland (PJM) market.

We observe that, by definition, $F(t, \tau_1, \tau_2)$ is a Q -martingale. This is in accordance with the no-arbitrage theory that states that all forward contracts must be martingales under the pricing measure. Observe that when t approaches start of delivery τ_1 , we do not, in general, have that $F(t, \tau_1, \tau_2)$ converges to the spot price. This is rather natural since the forward contract depends on the spot over a period of delivery, and not only at a fixed time of delivery. On the other hand, this is a distinct feature for electricity markets, which is not observed in most other commodity markets. An immediate effect of this is that one does not expect the same degree

of sensitivity to spot price variations in electricity forwards as for other commodities.

The range of spot models that allow for explicit electricity forward prices is rather limited. Much of the literature on commodities focuses on mean-reverting spot price models, and the exponential Ornstein–Uhlenbeck process (see **Ornstein–Uhlenbeck Processes**)

$$S(t) = S(0) \exp(X(t)) \quad (12)$$

where

$$dX(t) = \alpha(\theta - X(t)) dt + \sigma dB(t) \quad (13)$$

is the classical example; see [9]. This model has been generalized to allow for jumps modeling spikes (see [6] for the threshold model by Geman and Roncoroni). However, even though one can derive explicit expressions for the forward prices $f(t, T)$, it seems to be very hard to obtain the same for electricity forwards (see [4] for examples). On the other hand, arithmetic models as suggested in [2] seem to be appropriate for this.

The problem of choosing the right pricing measure Q can be approached from several different angles. The most common is by means of introducing a parameterized class of pricing measures Q , that is, pricing measures that depend on one or more parameters. These parameters will appear in the forward prices, and thus one may estimate them by calibration to observed forward prices. The relation between P and the estimated pricing measure $\hat{Q}$ would give us a statistical estimate on the risk premium in the market.

Benth *et al.* [1] propose to model the formation of forward prices from spot by using the certainty equivalence principle. Two representative agents, a consumer and a producer, decide whether to trade in the spot or forward market, based on where prices are more preferable. The certainty equivalence principle leads to forward pricing bounds within which the settled forward prices must lie. Introducing the market power as an explanatory variable, forward prices can be expressed in terms of the spot. Moreover, the risk premium is stochastic, and a positive premium in the short end of the forward curve is explicitly linked to the spikes in the spot, a feature which is in line with [7]. One may derive the risk neutral pricing measure for option pricing purposes. Empirical

support for this approach has been found in an analysis of spot and forward price data observed at the German electricity exchange EEX.

An alternative approach promoted in [3] is to use the *Heath–Jarrow–Morton* (HJM, see **Heath–Jarrow–Morton Approach**) idea from *interest-rate modeling* to electricity forwards. This entails modeling the price dynamics $t \mapsto F(t, \tau_1, \tau_2)$ for arbitrary delivery periods $[\tau_1, \tau_2]$. In fact, the application of HJM in electricity is not straightforward. At Nord Pool, say, the market trades in contracts with overlapping delivery periods, leading to certain price relations that must be met to avoid arbitrage possibilities. Benth and Koekebakker [3] show that this leads to rather strong restrictions on the feasible models; for instance, geometric Brownian motion with time-dependent volatility is ruled out. Furthermore, the connection to the underlying spot price is lost since there is no convergence of electricity forwards to the spot when time to delivery goes to zero. We refer to [3] and the monograph [4] for more discussion on these issues and empirical studies of data from Nord Pool where a market model (*LIBOR model*, see **LIBOR Market Model**) approach is taken.

End Notes

^aWe assume constant interest rate r and make no distinction between a forward and a futures contract.

^bAt Nord Pool, the settlement is with respect to the hourly spot price over the delivery period. This would entail a summation over the spot prices at the discrete hours. However, we choose to work with the slightly more notational convenient integration.

Commodity Risk

Before the emergence of B2B exchanges and the contracting innovations of interest here, the focus in procurement was on bilateral negotiation, and the literature provides analysis of many aspects of supply contracting in this setting (see [3] for a review). Bilateral contracting and traditional supplier management practices will remain essential elements of procurement management in the future. However, the growth of commodity exchanges, and derivative instruments defined on these, has introduced a fine-tuning mechanism that improves operational performance and simultaneously helps value longer term contractual, capacity, and technology decisions. The centerpiece of this new perspective is the integration of traditional forms of contracting with shorter term market-driven physical and financial transactions. This integration is the focus of this article.

An example will help clarify the scope and importance of this subject. Consider the beverage industry. Aluminum is an important element of the cost structure. For major buyers like Anheuser Busch, a restricted set of sellers is used to source aluminum, even though the aluminum spot market price is a key benchmark for sourcing and hedging, and is determined by the actions of scores of global players. Here, sourcing arrangements with main sellers are typically set according to the spot price plus processing costs, and contracts are marked to market on a daily basis. Second, there may be value-added services undertaken by these contractors to take aluminum ingots and prepare them in a more suitable fashion for can production, and again here this would be done only with specifications for these services worked out with a few sellers. However, the typical setup in metals is for a restricted set of contract sellers, with spot purchases and hedging used to benchmark prices and to “top up” contract purchases and hedge overall supply cash flows. The same general market and contracting structure operates in many other commodity markets, including energy and agricultural markets [5].

The first question to address is the consequence of competition among multiple sellers with heterogeneous costs/technologies. This question can be addressed in two ways: one is to assume a closed spot market in which all participants in the contract market also participate in the spot market, and *vice*

versa. Alternatively, one can assume an open structure in which the spot market price is determined by a larger group of competitive sellers than the smaller, restricted group operating in the contract market for a particular buyer. In this article, we follow the latter assumption; for a discussion of closed spot markets and strategic behavior, see [10].

A Primer on Previous Literature

The literature on contracting in economics has been driven by the transactions cost framework developed by Williamson [11], and subsequently formalized in the principal–agent literature [8].

A key question addressed in the economics literature has been the efficiency of various contracting structures. A well-known result in the economics contracting literature is due to Allaz and Vila [1], which examines the efficiency of pure forward contracts in an oligopolistic setting but with a deterministic spot market (which is fixed and common knowledge). Assuming homogeneous sellers and instantaneous scalability (with no capacity limitations), they show that forward markets can yield inefficient outcomes because of strategic use of these markets by sellers with market power. Wu and Kleindorfer [12] show that the Allaz–Vila-forward-market inefficiency disappears when options contracts are introduced into the mix of traded instruments, underscoring the importance of derivative instruments for supply management.

The financial economics literature provides basic pricing results for derivative instruments traded on standard contracts in liquid markets. In the context of supply contracting, an additional distinction is required in the types of options involved, between purely financial options and those connected to physical delivery of a particular good at a particular time and place. The early discussion and literature was focused on physical delivery options to fulfill a buyer’s sourcing needs. These options would entail delivery at a particular time and place (e.g., FOB Pittsburgh). In these markets, options backed by physical delivery are central to the buyer’s problem of arranging for sufficient supply to meet the buyer’s demand. However, once a functioning spot market exists, this market can be used to define financial options on the basis of the spot price. Major buyers then find it in their interest not only to arrange optimal sourcing from the contract and spot markets for

physical delivery of goods but also to use the financial options defined in the market for price discovery and as risk hedge instruments. As Birge [2] notes, if either revenue or costs associated with a given product line are correlated with some well-defined price (or cost) index arising from a competitive market, then this price index can be used to define an appropriate derivative or options instrument that provides not only risk hedging benefits but also valuation information for the underlying operations decisions whose outputs are correlated with the index.

Standard Commodity Hedging Framework

The standard approach to supply management commodity risk [5, 12] is based on the following three-period timeline for trading in the B2B exchange, either using contracts or using the spot market (Figure 1).

- Period 0: At period 0, capacity and technology choices are made by buyers and sellers. As shown in [5], these choices will be different when rational managers know that they can fine-tune demand and supply through the spot market than when such a possibility does not exist.
- Period 1: At period 1, with updated information on the distribution of spot prices, sellers and buyers contract with one another, using options and forwards, for delivery of some good (either storable or nonstorable) at period 2.
- Period 2: Finally, at period 2, after possibly updating additional information, options are called, forwards are executed, deliveries are made, and additional sales and purchases are made in the short-term spot (or cash) market.

Between period 1 and period 2, there may be additional trading of options and additional, possibly continuous, updating of information on spot prices. The analysis here will assume a discrete-time framework with no secondary trading. Thus, we are only concerned with the indicated decision instants at periods 0, 1, and 2.

The objective of the buyer is to maximize expected profit by choosing among the available forward and spot contracts. The objective of sellers is to maximize expected profit, jointly obtained from sales in both the contract market and the spot market and subject to the seller's capacity constraint. Either buyer or sellers may have additional risk-based constraints on their transactions, such as those derived from a Value-at-Risk (VaR) framework, as explained further subsequently.

A key factor influencing the incentives of sellers and the buyer to sign contracts is the existence of imperfect market access on the day, capturing possible access inefficiencies of the spot market, which includes cost and quality differences between contract markets and the spot market. In addition, in supply management for commodities, different grades and specifications for commodities often require prior contracting and procurement relations. These alternative situations give rise to various forms of commodity risk management, as shown in Table 1.

Access conditions are modeled in [12] *via* a function $m(P_s)$, which is defined as the probability that the seller can find a last-minute buyer on the spot market when the realized spot price is P_s . This market access probability can also be thought of as the proportion of the seller's capacity that can be expected to be sold at the last minute. This function may be thought of as a measure of the liquidity of the market and the degree to which the commodity in question is standardized. When quality and yield issues are present, then $m(P_s)$ may also be

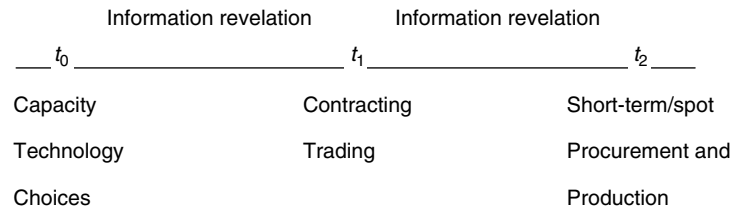

Figure 1 Market interactions in the standard commodity hedging framework

Table 1 Alternative contexts for commodity risk management of supply

Description of context	Instruments used in optimal portfolio	Examples
Cost and access differences are small and only standard commodities are sourced	Bilateral contracting and financial hedge instruments are defined on a common market and optimized jointly	energy commodity metals
Cost and access differences are large and only standard commodities are sourced	Bilateral contracting is used for most physical procurement, with spot market used for topping up supply, and for financial hedge instruments	Logistics services (standard air and maritime cargo) Fed cattle (beef), hogs, and lamb markets
Nonstandard commodities are sourced, but their prices are highly correlated with those of standard commodities	Bilateral contracting is used for all physical procurement, with financial hedge instruments, defined on correlated standard products, used as an overlay	Plastic resins and commodity chemicals

thought of as the quality risk associated with spot purchases.

The standard problem of commodity sourcing and hedging for a buyer can be stated as follows (this is the problem facing the buyer at period 1 in Figure 1):

$$\text{Maximize } E \left\{ \Pi(Q, \tilde{D}, \tilde{P}_s) \right\} \quad (1)$$

s.t.

$G(Q, F_D, F_{P_s}) \geq 0$ physical delivery constraints

$H(Q, F_D, F_{P_s}) \geq 0$ VaR constraints

$Q \in X$ other constraints on instruments

where the maximization in equation (1) is over the vector of available financial and physical instruments Q at the time of contracting, where “demand” uncertainties are represented by $\tilde{D}$, and where spot price uncertainty is represented by the random variable $\tilde{P}_s$, with respective cumulative density functions of F_D and F_{P_s} . At period 2, of course, once D and P_s are observed, instruments are executed to fulfill the physical delivery constraints and to optimize profits on the day by executing all options that are “in the money”, or needed for physical fulfillment. This problem “on the day” can sometimes be interesting, but it in theory is straightforward and we do not consider its solution here. Various forms of the problem in equation (1) have been developed for various types of markets, and the details for these differ considerably across these markets. To illustrate, let us consider the structure of this problem for the case of a distribution

company or supplier in the case of electric power operating in the presence of a liquid spot market.

Electric Power: An Illustrative Example of Commodity Hedging

We imagine an integrated utility, called the *Company*, which may own or lease generation, and which has a trading division that can sign contracts for power purchase agreements (PPAs), as well as puts, calls, and forwards, based on an underlying wholesale spot market. We abstract here from transmission constraints or markets.^a For simplicity, we also imagine that the Company provides energy to retail customers at prices that are regulated. We will take the simplest possible approach to the regulated sector, assuming a fixed, exogenously determined regulated price per Kilowatt hour, independent of time. More complicated regulatory scenarios are easily incorporated into the framework developed. This feature of customer demand at regulated prices, together with the weather-driven level of spot prices and the nonstorability of electric power, makes electricity supply a risky business.

We are interested in formulating the Company’s optimal portfolio problem for procuring and hedging its purchases of energy. The portfolio will be characterized by different levels of time-indexed instruments (puts, calls, forwards, etc.) that might be called upon either to fulfill retail demand or simply as part of profit-oriented trading/hedging activities by the Company’s trading division. We refer

to all potential assets for the portfolio, including owned/leased generation and PPAs, as *instruments*.

Following [6] and [7], we think of each instrument as having a capacity (measured in megawatts) that can be called or sold in a specific period (consisting of specified hours during a given week or month, typically the 5×16 h of “peak” or the 7×8 h of “off-peak”). Each instrument entails a reservation price, possibly zero, per megawatt to reserve, and an execution price, per megawatt hour, if used. In this framework, instruments such as own generation and certain PPAs that have been precommitted have a fixed execution price (e.g., the marginal running cost of own generation), but may be thought of as available at a reservation price of zero. Purchased forwards, which are prepaid, fixed obligations to deliver power, may be viewed as call options having a zero execution price that therefore will be executed by the Company on the day. Forwards sold by the Company have the same characteristic, that is, they may be viewed as options contracts with a zero execution price (that therefore will be executed on the day).

To set up the model, we will assume that the planning period for the instruments in question is a month, with hours in the month being denoted by the set $T = \{1, \dots, 720\}$. We will consider additional subsets of T below, such that certain instruments may be valid only for certain subsets of time (e.g., peak hours). We need the following additional notation:

Q_i = the amount (in megawatts) of instrument i that is purchased/sold

r_i = reservation price per megawatt hour for call asset i^b

c_i = execution price per megawatt hour for call asset i

s_i = reservation price per megawatt hour for put asset i

p_i = execution price per megawatt hour for put asset i
 $T_j \subseteq T$ = index of those hours of type “ j ”, where $j = 1, \dots, J$ (types of time periods might be, for example, peak periods, off-peak periods, week-ends, etc.)

I_{cj} = the set of indices for all call instruments (used in the following summation) that can be executed during hours of type j

I_{pj} = the set of indices for all put instruments (used in the following summation) that can be executed during hours of type j

n = the number of all instruments (so $n = \sum_{j=1}^J |I_{cj} \cup I_{pj}|$)

m_i = lower bound or minimum amount allowed for instrument Q_i

M_i = upper bound or maximum amount allowed for instrument Q_i

The random variable of “monthly cash flows” depends on the level of each instrument Q_i in the portfolio, where some instruments, within each month, may apply to different periods of time (e.g., just the peak periods or just the off-peak periods, or to some other selection of periods). We can write cash flows (for some period, say month t) in the following general form:

$$\begin{aligned} \Pi = & \sum_{\tau \in T} (P_{c\tau} - P_{s\tau}) D_{c\tau} \\ & + \sum_{j=1}^J \sum_{\tau \in T_j} \left[\sum_{i \in I_{cj}} [(P_{s\tau} - c_{i\tau})^+ - r_i] Q_i \right. \\ & \left. + \sum_{i \in I_{pj}} [(p_{i\tau} - P_{s\tau})^+ - s_i] Q_i \right] \end{aligned} \quad (2)$$

where $\tau \in T$ are the subperiods within the month in question, each assumed to be of length 1 h, and where we have indexed spot price P_s and the execution prices c_i and p_i for the options by time periods, in case these execution prices are time sensitive (e.g., different prices for peak or off-peak periods for the same instrument). Note that once an instrument is purchased, it is available for all hours covered by the instrument (e.g., a peak-period call option of Q_i MW is available for any peak hour in the month, subject to requirements—usually 24 h in advance—to execute the option).

Using equation (2), it is easily seen how this problem fits the standard form of equation (1). The profit function is clear (though additional payments to capital providers would be accounted for as in equation (2) in the risk constraint). As for the physical fulfillment constraints, these are also straightforward as long as the spot market is completely reliable as a source of power on the day (and very high reliability is typical of such markets). The VaR constraint in

equation (1) is represented as

$$\Pr \left\{ \Pi(Q, \tilde{D}, \tilde{P}_s) - F \geq -VaR \right\} \geq \gamma \quad (3)$$

where $\Pi(Q, \tilde{D}, \tilde{P}_s)$ are the cash flows in equation (2) resulting from the vector of contracts Q , where F represents fixed capital payment obligations, and VaR is the maximal Value-at-Risk allowed for the period in question, with confidence level γ (see **Value-at-Risk** and also [4, 9] for a discussion of VaR). In the case where there are sufficient subperiods in T to make the normality assumption reasonable for $\Pi(Q, \tilde{D}, \tilde{P}_s)$, this standard VaR constraint translates into a simple function of the mean and standard deviation of $\Pi(Q, \tilde{D}, \tilde{P}_s)$. Since the profit function is linear in Q_i for every realization of the random variables involved, finding the efficient frontier (in $E\{\Pi\}$, VaR space) is then easily solved in the standard fashion *via* quadratic programming. Multiperiod VaR constraints are also discussed in [7]. For more complex problems that arise in practice, including sophisticated models of the evolution of the spot price and various exotic options, Monte Carlo simulation (see **Monte Carlo Simulation**) with an appropriate optimization engine can be used.

Implementation and Research Challenges

It is unfamiliar territory for most organizations to integrate finance and supply management, and this is precisely what is required in order to have the full benefit of the options approach described here. Companies wishing to do so must radically expand the traditional focus of procurement on cost, quality, and dependability to include tracking of spot market conditions, valuing options in operational and hedging terms, and linking these activities to an appropriate risk management structure. Companies that have done this well have recognized the need to develop capabilities in trading, data management, and financial reporting and management. These include new skills in pricing and valuation of contracts, new approaches to managing the portfolio of sourcing options for key manufacturing inputs, and a very different approach to customer and customer segment valuation and management.

The open questions associated with B2B exchanges and contracting can be described under two general headings. First are the model-based

developments needed to capture the essence of the supply–demand coordination problem and the necessary options-based instruments to achieve efficiency in particular market contexts. Second is the continuing development of theory to understand the necessary guidelines for the structure and governance of sustainable business models for the exchanges supporting these instruments. Open research questions in these areas are noted in all of the references listed, especially in [5].

End Notes

^a.To the extent that these are based on principles of locational marginal prices, transmission constraints and options could also be included as part of the portfolio optimization described below.

^b.Thus, to reserve Q_i MW of callable capacity during a specific period of length L , the price paid is $r_i Q_i L$, where the maximum reserved/callable capacity during any hour of the period is Q_i MW. The reader can think of the reservation price in dollars per megawatt hour as the allocated cost to each hour of the period in question, though instruments will be typically traded for groups of hours in a month, for example, 100 MW of capacity callable for any peak hour during the month.

Commodity Trading

Considerable concern has grown around speculative opportunities in commodity markets, which attracted hundreds of billions of dollars in recent years. In February 2008, a Reuter news item announced that “London coffee, cocoa and sugar futures rallied (...) to multi-year peaks as investment funds and speculators shifted money into soft commodities in search of stellar returns.” In July 2008, Brent oil was quoted at its historical peak of 174.27 USD per barrel, before losing about 70% of that quote four months later (December 2008). Equally significant changes occurred in the prices of cotton, coffee, wheat, soybeans, corn as well as aluminum and copper.

Since unit production costs of agricultural and nonagricultural commodities did not vary so extensively in the same period—nor did consumption—we cannot just attribute the recent marked price changes to their fundamentals. Commodity index funds, hedge funds, and speculators are, therefore, the center of huge fluctuations, changing vastly the drivers of commodity markets.

Speculative opportunities are an obvious reason for this wide interest.

In oil futures markets, a significant role of speculation has been identified to explain the large daily upward and downward shifts observed in prices [3]. Thus, even these extremely liquid instruments suffer from liquidity shocks that induce periods of increased volatility and significant returns predictability [12]. These authors conclude that the oil futures market is not driven only by fundamentals.

Empirical papers have reported evidence of predictability in commodity markets (see among others [14, 17, 20]). Moreover, theoretical contributions [5, 6, 21] attribute a key role to inventories to limit extreme price fluctuations, recognizing at the same time that inventories introduce predictability on (storable) commodity prices.

Finally, the attraction to speculation on commodity markets can be self-induced.

“Herd behavior” on the side of speculators [7] or “excess consensus” [22] can exacerbate price movements in commodity futures markets and large storage owners can profit from large price deviations. Spurred by the growing attention of specialized press and by the academic evidence showing that commodity

futures portfolios can be managed similarly to equities portfolios [16], the investment industry started offering products, allowing individuals and institutions to “invest” in commodities through several derivatives and structured notes. The performance of such products can be compared to that of popular commodity indices (e.g., Sachs commodity index) and have allowed some authors, as Domanski and Heath [9], to introduce the term *financialization* of commodity markets.

In commodity markets, predictability is essentially equivalent to mean reversion of prices as several theoretical and empirical contributions have shown (e.g., [1, 4, 10, 18] for securities [24], for commodities, and [8, 19] for electricity).

In their theoretical analysis on the role of inventories, Deaton and Laroque [5, 6] observe that the price boundaries introduced by inventory owners turn out to generate mean reversion in the price process.

From an empirical point of view, Elam [11] observes that the price of December cotton futures (at planting time) helps forecasting the cotton price at harvest. In particular, when futures price is higher than its long-term average, spot price tends to be lower and *vice versa*. This is exactly a mean-reverting behavior.

In their empirical analysis of several commodity markets [2], the authors adapt a simple trading strategy to exploit significant mean reversion observed in the corresponding price processes.

Till [25] takes into consideration two historically profitable trading strategies based on the mean-reverting properties of commodity prices.

Predictability and the relevance of mean reversion on commodity markets have also been contrasted, as in [23]. Nevertheless, the authors cannot deny the significance of mean reversion over periods longer than six months.

This evidence justifies the interest of this work. We devise optimal boundaries for the entry and exit timing of a trading strategy in a mean-reverting market.

Since our strategy is based on the peculiar properties of a mean-reverting stationary price process, it is important to observe that as long as such a strategy remains profitable, the presence of a mean-reverting stationary behavior is confirmed.

The Trading Strategy

Consider a mean-reverting process of an asset price x on which a long and a short position can be taken (such as a spot or a forward contract). The process can be described by the following stochastic differential equation (SDE):

$$dx = -\lambda(x - \Phi)dt + \theta dW \quad (1)$$

where λ is the continuous speed of reversion, θ the diffusion coefficient, and Φ is the long run average. If we consider discrete time intervals of length Δt , the corresponding discrete autoregressive process is

$$x_{t+1} = x_t + k(\Phi - x_t) + \sigma \varepsilon_{t+1} \quad (2)$$

where $k = 1 - e^{-\lambda \Delta t}$, $\sigma^2 = \frac{1 - e^{-2\lambda \Delta t}}{2\lambda} \theta^2$ and $\{\varepsilon_n\}$ are independent and identically distributed $N(0, 1)$. As soon as the process x_t diverges from Φ , the drift adjusts instantaneously to revert back to Φ . The reversion speed depends on k ($0 \leq k \leq 1$). The case $k = 0$ corresponds to a random walk.

To keep things simple, we assume that the long run average is a constant. Still, we are aware that for long-term trading strategies, it could be worth considering the inflationary or other trend elements of this average. Our one-factor process limits the shape of the forward curve more severely than it actually happens. Further, the long run average could be stochastic itself. This can be a key factor that makes the process nonstationary [15]. On the other hand, in the empirical application that follows, we will see that a constant long run price average is statistically consistent at the usual levels for several markets. Besides, the assumption of a constant Φ can be reasonable for finite (especially short) horizon strategies and has the advantage of improving the mathematical tractability.

We consider a strategy that is very close to a simple buy-and-hold. For ease of illustration, we account only for profits and losses, ignore the margin requirements, and do not consider transaction costs. We assume a zero-risk-free rate.

In a trading horizon $[0, T]$ choose $a > 0$ and construct two barriers around Φ : $\Phi + a$ and $\Phi - a$, respectively, the sell and buy barriers. Let $t^* \in [0, T]$ be the first time when $x_t \geq \Phi + a$ or $x_t \leq \Phi - a$, that is, when the price first crosses one of the two boundaries. A short or long position is then started

depending on which one of the two conditions is verified first.

Suppose that x_t goes below $\Phi - a$ in t^* , so one can take a long position (buy the asset on the spot market or a future/forward contract) for the nominal value of $\Phi - a$. The position can be closed in two ways. In the first case (*full closing*), the position is closed if $x_t \geq \Phi + a$ for some $t < T$; the net profit is $2a$. There is, however, the possibility that such a condition is not met before T . In this case, the position is closed at price x_T , with a random profit/loss $x_T - (\Phi - a)$. Analogously, the strategy is started with an opposite sign (short position) if $x_t \geq \Phi + a$ in t^* . If $t^* \notin [0, T]$ (i.e., x_t remains within the two boundaries over all the trading period), the strategy is not started and the net profit is 0 (Table 1).

This trading strategy can be implemented on the spot (respectively, futures) market, assuming that x_t is the spot (respectively, futures) price. In the case of commodity spot markets, some additional technicalities are required, such as borrowing/lending the commodity in a self-financing position. Such aspects do not alter our results. Further, by assuming a zero interest rate and equally balancing the frequencies of long and short positions, we do not need to account for gains and losses generated by borrowing/lending positions.^a

The expected profit can be optimized with respect to a under two different strategies:

1. no bounds on the full closing probabilities (maximum return strategy, MRS):

$$\max_a E[G(a; k, \sigma, T)] \quad (3)$$

2. a lower bound of 95% on the full closing probabilities (fixed risk strategy, FRS)

$$\begin{aligned} \max_a E[G(a; k, \sigma, T)] \\ \text{s.t. } p_{11} \geq 0.95 \end{aligned} \quad (4)$$

where p_{11} is the full closing probability.

Table 1 Plot of decision bounds over the price series. Outcomes of a trading strategy (time horizon T , boundaries $\Phi + a$ and $\Phi - a$)

		x_t goes above $\Phi + a$ before T	
		Yes	No
G	Yes	$2a$	$x_T - (\Phi - a)$
	No	$(\Phi + a) - x_T$	0

FRS is a VaR-like strategy as the “risk” involved in the strategy is constrained under the 5% probability of not having a full closing. We solved equations (3) and (4) numerically, searching for the optimal a on a large grid of k and T by a Monte Carlo simulation based on 2.727×10^7 trajectories. For more details, see [13].

The Risk–Return Trade-off

MRS. Simulations show that for every pair (k, T) there is a bound maximizing the expected profit. From Figure 1(a) we see that, in general, the maximum expected profit increases with T , but the effect is more pronounced for relatively low values of k , which for practical purposes is very interesting. From

Figure 1(b) (MRS depending on k for several values of T), we note that at short maturities MRS increases with k , while for longer maturities the expected profit is not monotonic: a positive reversion speed is required to generate positive expected profits; however, if it is too strong, it keeps the process close to the long run mean, reducing the profit opportunities generated by the diffusion.

FRS. Figure 2 shows the dependency of a on T and k . As a function of k (Figure 2b), short-term and long-term strategies differ: for short terms, faster reversion coefficients k imply higher closing probabilities (and so a larger a and a larger expected profit), but when the time horizon is high, an excessively strong reversion reduces the optimal bound and the

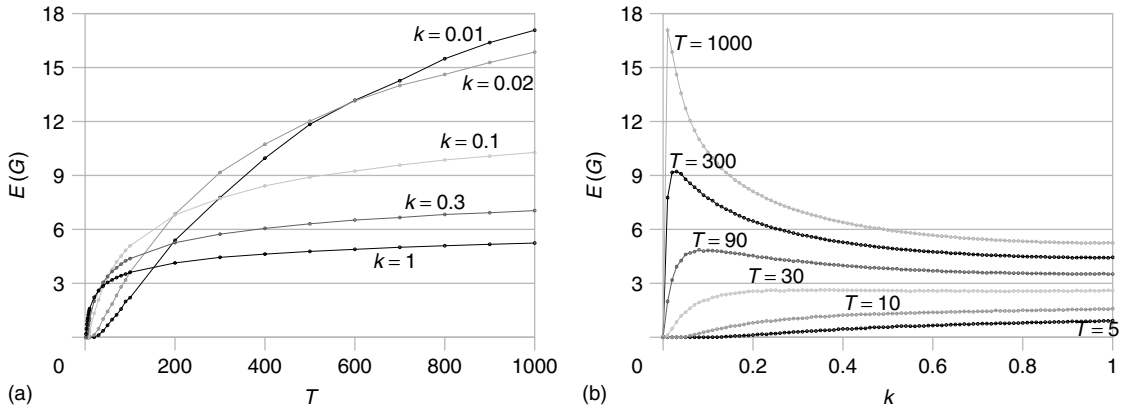

Figure 1 (a) MRS vs the maturity T for $k = 0.01, 0.02, 0.1, 0.3, 1$. (b) MRS vs the reversion k for $T = 5, 10, 30, 90, 300, 1000$

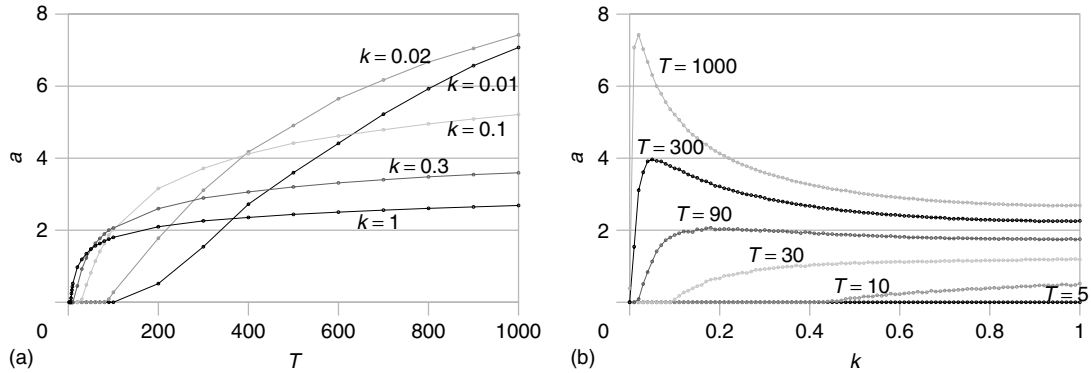

Figure 2 (a) The optimal bound a_{FRS} vs the maturity T for $k = 0.01, 0.02, 0.1, 0.3, 1$. (b) The optimal bound a_{FRS} vs the reversion k for $T = 5, 10, 30, 90, 300, 1000$

expected profit accordingly. For every large T , there is a k maximizing the full closing probability.

The Empirical Evidence

We collected the series of 6931 daily prices of nearby futures contracts of live cattle, cotton, gas oil, copper, wheat and sugar for the period January 1, 1981 to July 27, 2007. We simulated a trader taking a short/long position during a time interval j . The position is taken only once on the basis of the trading signals suggested by the optimal values of a calculated on data available up to the interval $j - 1$. The strategy starts only if a significant stationary mean reversion is observed up to $j - 1$. We evaluated the profit/losses generated by the two trading strategies, MRS and FRS, over several subperiods obtained by splitting the original series in intervals of different length (30, 50, 70, 100, 200, 300, 500 trading days).

As a refinement of those strategies, when selling or buying conditions are met (i.e., $x_t \geq \Phi + a$, $x_t \leq \Phi - a$), trades occur at price x_t instead of the boundary value. The strategies remain the same, but the order execution is similar to what is known as a *best price order* (the investor fixes a boundary price,

then the market trader executes the order at the best price available on the book satisfying the boundary).

Estimates and tests of stationarity and reversion speed are shown in Table 2. The stationarity test is based on a standard augmented Dickey–Fuller’s τ (Prob(τ) is the rejection probability under the null hypothesis that the series is stationary). The significance of the reversion speed parameter is given by a t -test on the ordinary least squares (OLS) regression 1 (Prob(k) is the rejection probability under the null hypothesis $k \neq 0$). Live cattle and cotton are significantly stationary and mean reverting. For gas oil and copper, stationarity is rejected, mainly due to the marked rise in prices that has occurred in the recent years; as a consequence, the reversion speed coefficients are not significantly different from zero. Coffee and wheat are not stationary, while their reversion coefficients are significant at 5% level.

Tables 3 and 4 report the results of MRS and FRS, respectively. To make results comparable among commodities, profits and losses are expressed as an average of all profit/losses under each maturity and are normalized as a percentage of the corresponding historical average price. Thus, figures may be taken as the average “rate of return” obtained by applying the strategy on one unit of the underlying commodity over a period of length T . A t -test assesses the statistical significance (1%, 5%).

FRS and MRS show a similar pattern, with MRS offering higher average profits as expected. Trading in live cattle gives on average sizeable MRS profits for $T = 100, 200, 300$, and 500. Cotton offers MRS positive returns (of a lesser size) for $T = 30, 100, 300$, and 500. Gas oil and copper show negligible or even significant negative returns (with an isolated exception for gas oil at $T = 500$): this is due to the nonstationarity of the series and the recent steady rise

Table 2 Stationarity test and significance reversion speed estimates and significance

in prices. Under such conditions, prices do not reverse within the chosen boundaries. Thus, according to our strategy, the position is opened often, but is seldom “fully” closed.

Coffee for $T = 300$, 500 and Wheat for $T = 300$ (and also $T = 500$ for MRS) show FRS statistically significant negative expected returns (of a relevant size for wheat). Our trading strategies would have offered significant positive returns if applied with opposite trading signs.

The empirical outcomes confirm the theoretical expectations only for live cattle and cotton, where both stationarity and mean reversion are statistically acceptable. The other commodities, for which stationarity is weak or not significant, offer significant positive returns only on a strict range of the trading intervals or even show significant losses. The lack of stationarity of gas oil, copper, and coffee generates average losses almost over all maturities. Puzzling results as returns turning from positive (for shorter maturities) to negative (for longer ones) may be explained by markets mixing “momentum” and “reverting” regimes, where prices revert to their historical average in the short run but tend to systematically diverge on longer observation periods. This is the case of wheat from 1986 to 1995 or from 1998 to 2007.

Conclusions

We proposed a trading rule exploiting the peculiarities of a mean reversion process and investigated the related properties. The empirical results confirm the simulation analyses and show how our strategies perform nicely in markets that are stationary and mean reverting.

Such results lead to some relevant conclusions about the current hypothesis of mean reversion in commodity markets. Mean reversion can be a relevant component of the process governing many commodities. However, our results, in particular for wheat, are more consistent with markets showing regimes switching from reversion to momentum and back.

Moreover, commodity prices are not always stationary. Metals and energy prices were relatively stationary for a long time, but experienced a strong positive trend in the recent years. Many agricultural commodities mix trend with stationarity. The opportunity to fruitfully adopt our strategies is, therefore, linked to the ability of discriminating, for each commodity, stationarity from momentum market phases, which can be an easier task than forecasting size and sign of the future price changes. In such a case, switching from a momentum to a mean-reverting strategy can be a useful practice for many investors and traders.

End Notes

^aIn a risk-neutral setting, a zero interest rate implies the absence of trend for any traded asset.

Commodity Forward Curve Modeling

Commodity Futures and Forward Prices

For several centuries, commodity forward markets have been the main place of commodity trading, as they allow producers and consumers to manage commodity price risk without going into actual delivery of a commodity. Forward contracts are traded over-the-counter between two parties and the grade of commodity, delivery point, exact amount, and exact delivery date are specified at the time of writing the contract. In this respect, they are different from *futures contracts*, which are standardized in terms of the grade, amount, delivery date, and location. Commodities are traded on exchanges such as the London Metal Exchange (LME), Chicago Board of Trade (CBOT), Chicago Mercantile Exchange (CME), InterContinental Exchange (ICE), and New York Mercantile Exchange (NYMEX). These futures markets provide the most reliable and liquid commodity futures prices. For example, most of the trading activity in oil markets takes place in futures and forward contracts, where the volume of trades is almost 10 times higher than in the spot market.

Throughout the article, we denote the commodity futures or forward price on day t for maturity date T by $F(t, T)$ and the spot price (i.e., the price for the immediate delivery) on day t by $S(t)$. The forward curve prevailing on day t is the collection of futures prices $\{F(t, T)\}_T$ for all traded maturities $T = 1, 2, \dots, N$. It has been known for some time that, in absence of credit risk, forward and futures prices are equal under nonstochastic interest rates [5]. In commodity markets, interest rate risk plays a secondary role compared to the commodity spot price risk, so we use the terms “futures price” and “forward price” interchangeably.

Forward curves are of paramount importance in commodity markets, for several reasons. They provide information about the views of market participants, anticipated price trends, and expectations about future supply and demand. Futures prices observed in liquid futures markets provide price discovery and are essential for daily marking to market existing portfolio positions as well as for risk management

activities such as Value-at-Risk calculations. Forward commodity prices influence storage, production, and other strategic decisions in related industries. Finally, futures contracts provide the way of calibrating derivatives pricing models under the risk-neutral probability measure.

The spot price of a commodity is often considered as the most important factor driving the whole forward curve [6, 13]. The influence of the spot price becomes greater as the futures contract approaches maturity, culminating in the following convergence property: on maturity date, the futures price must coincide with the spot price

$$F(T, T) = S(T) \quad (1)$$

This property follows from the absence of arbitrage and the possible occurrence of physical delivery of a commodity at the maturity of the futures contract. However, there are markets where the spot price is rather opaque or unreliable (or completely nonexistent, as it is the case, for instance, in electricity markets). In such cases, the convergence property does not necessarily hold or does not take place smoothly as the maturity approaches. These considerations, among others, may question the suitability of the spot price as the main driving factor of the forward curve.

Crude oil (and some metals) forward curves have traditionally been in one of the two states: backwardation, when the futures prices for short maturities are more expensive than those maturing later, or contango, which is the opposite situation. Figure 1 shows the NYMEX crude oil forward curve on February 21, 2008, when the market was in backwardation, and Figure 2 shows a contango forward curve observed on February 28, 2007.

Whether the market is in backwardation or in contango depends on the current price as well as inventory levels, transportation and storage costs, supply of storage, supply and demand equilibria, strategic and political issues, and many other factors. The shape of the commodity forward curve is closely related to the notion of the so-called *convenience yield*, that is, the benefit of holding a physical commodity over a futures contract. Backwardated forward curves arise when the benefit of holding a physical commodity (i.e., the convenience yield) is high and the interest rates and storage costs (representing together the “cost of carry”) are relatively low. This happens, for instance, when there is a general perception of

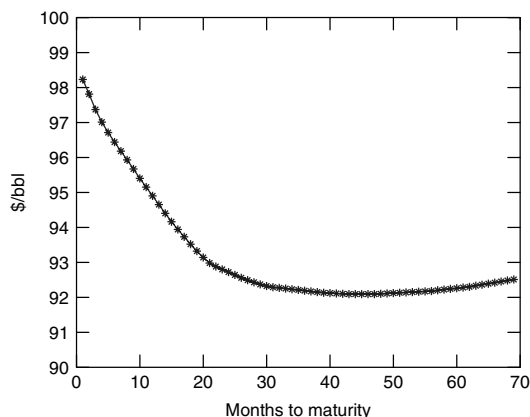

Figure 1 NYMEX crude oil forward curve, February 21, 2008

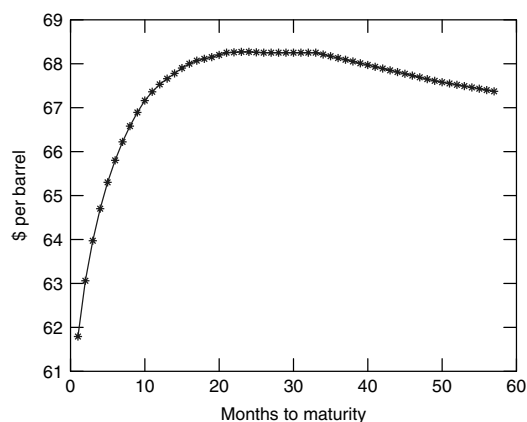

Figure 2 NYMEX crude oil forward curve, February 28, 2007

low availability of a commodity and instability of its supply. More generally, the shape of the forward curve summarizes perceptions of market participants about the current state and future developments of the global commodity market.

For seasonal commodities, such as natural gas, electricity, or agricultural commodities, futures prices are largely governed by seasonal demand (as it is the case for energy) or supply (for agricultural commodities). For those commodities, transportation or storage capabilities are limited, so the excess demand or supply shortage cannot be absorbed by transporting a commodity from a different part of the world with excess supply, or storing at times of plentiful supply and using it whenever necessary.

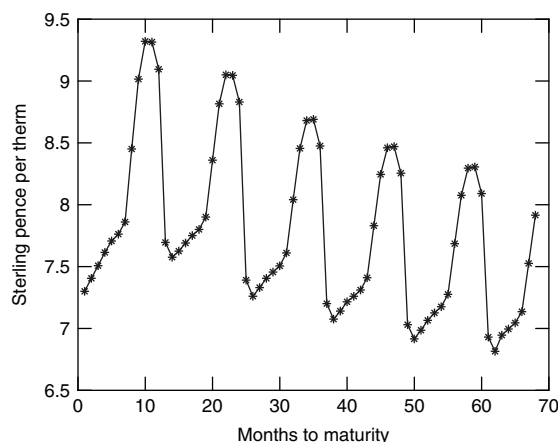

Figure 3 UK Natural Gas forward curve, March 7, 2007

This results in a high seasonal premium on futures contracts maturing during periods of high demand (such as winter, in the case of natural gas) or low supply (such as before harvest, for agricultural commodities). This is illustrated in Figure 3, where a forward curve for natural gas in the United Kingdom is shown. Futures maturing in the winter (the time of high demand for gas in the United Kingdom) are clearly at a premium compared to those maturing in summer.

The dynamic modeling of the forward curve (i.e., the description of its random movements over time) and the understanding of the main fundamental factors behind its evolution has been a subject of extensive research, both by practitioners and academics. A proper model of the dynamics of the forward curve is an essential input in most derivative pricing models, scenario simulation, and risk management applications. A successful forward curve model should be able to match current observed forward curves, generate realistic forward curves containing empirically observed features, and should ideally be able to extrapolate the forward curve beyond the longest observed maturity. Moreover, it should be easily and quickly calibrated to the market data. However, just as in case of the Treasuries yield curves, commodity forward curve modeling is a challenging task, owing to the inherent multidimensionality of the problem and a nontrivial dependence structure across maturities. In contrast to interest rates, features such as seasonality may further complicate the modeling process.

Forward Curve Models

Forward curve modeling approaches for commodities can be loosely classified into three main categories. The first one is a martingale-based approach, which models the dynamics of futures prices directly under the risk-adjusted probability measure Q , making use of the fact that futures prices are martingales under such a measure. One or possibly several risk factors driving the risk-neutral dynamics of the entire forward curve are usually assumed (resulting in the so-called *one-factor* or *multifactor models*).

Multifactor models such as those described in [4] are similar to the celebrated Heath–Jarrow–Morton (HJM) approach for modeling the yield curve [7], in that they directly model futures prices under the risk-neutral probability measure.^a So the following representation is often considered:

$$\frac{dF(t, T)}{F(t, T)} = \sum_{i=1}^n \sigma_i(t, T) dW_i(t) \quad (2)$$

where n is the number of risk factors, $W_i(t)$, $i = 1, \dots, n$ are Brownian motions (possibly correlated) representing sources of uncertainty and $\sigma_i(t, T)$ are volatilities associated with the risk factors (possibly varying deterministically in time and maturity). The statistical technique of *principal component analysis* is often used to derive the risk factors, in which case they are assumed to be uncorrelated. Such an approach focuses on the martingale property of $(F(t, T))_{t \leq T}$ under Q , which is useful for derivatives pricing. However, it is less suited for trading strategies involving spot and forward positions (the most common ones in a trading environment), as it says nothing about the actual evolution of the forward curves and hence cannot be calibrated to historical futures market data. The risk factors can be rather arbitrary and do not always have a clear meaning.^b Alternatively, more interpretable fundamental stochastic factors can be taken. For example, a popular choice is to take the short-term and long-term price components (e.g., [10, 14]), which together determine the commodity's spot price:

$$S(t) = s(t) + X(t) + L(t) \quad (3)$$

where $X(t)$ and $L(t)$ are respectively the short- and long-term price components and $s(t)$ is a possible (deterministic) seasonal component of the spot price.

Then the futures prices are obtained using the relationship

$$F(t, T) = E_Q(S(T) | \mathcal{F}_t) \quad (4)$$

where Q is the risk-adjusted probability measure and $\mathcal{F}_t$ is the information available up to date t . To evaluate the expression (4), the dynamics of the fundamental factors (such as $X(t)$ and $L(t)$) under the risk-adjusted probability measure Q should be specified. Usually, such dynamics include the market prices of risk (the spot price risk and convenience yield risk), which make these models rather hard to calibrate, as market prices of risk are not observable. Another problem with such models is that the forward curves derived from equation (4) usually do not match observed forward curves.

Another approach to the commodity forward curve modeling is a static arbitrage-based one, making use of the cash-and-carry arguments and describing the no-arbitrage relationship between the spot and futures prices. This approach is based on the no-arbitrage assumption and implies that the futures price of a commodity must be equal to the cost of acquiring the physical commodity and carrying it until the maturity of the futures. Physical commodities, unlike financial assets, cannot be stored costlessly; so for them, the cost of carry is largely determined by the accumulated storage costs (and the interest lost on the investment into a commodity). However, these arguments would imply that commodity forward curves should always be in contango, that is, futures prices for longer maturities should always be higher than those for shorter maturities and the spot price. In practice, this is rarely the case; for example, historically, the crude oil futures market has been in backwardation approximately 75% of the time. To cope with this observation, the notion of *convenience yield* was introduced by Kaldor [8] and Working [15]. It is defined as the premium received by the owner of the physical commodity and not accruing to the holder of a futures contract written on it. This concept leads to the famous cost-of-carry relationship:

$$F(t, T) = S(t)e^{[r(t)+c(t)-\tilde{y}(t)](T-t)} \quad (5)$$

where $r(t)$ is the riskless interest rate on the date t , $c(t)$ is the storage cost (per unit of time and per dollar worth of commodity), and $\tilde{y}(t)$ the convenience yield, all continuously compounded. Often, the convenience yield is defined net of storage costs: $y(t) = \tilde{y}(t) -$

$c(t)$, in which case the cost-of-carry relationship becomes

$$F(t, T) = S(t)e^{[r(t)-y(t)](T-t)} \quad (6)$$

In its early versions, the cost-of-carry relationship (6) included a constant or deterministic (but time-varying) convenience yield, such as in [3]. The next step was to define the convenience yield as a function of the spot price. More realistic versions of equation (6) (e.g., those in [6, 9]) included the convenience yield as a stochastic process. Some authors stressed a time-spread optionality embedded in the convenience yield (discussed in, e.g., [12]). To emphasize this option-like feature of the convenience yield, it should be considered as a function of maturity T (or time to maturity $T - t$), as well as time t : $y = y(t, T)$, as suggested in [2]. This representation is particularly useful in the case of seasonal commodities.

Obtaining a dynamic model for the forward prices from the cost-of-carry relationship (6) goes as follows. The spot price $S(t)$ and the convenience yield $y(t)$ are considered as the main fundamental stochastic factors driving the forward curve's evolution. A stochastic model is assumed for the joint dynamics of $S(t)$ and $y(t)$ (e.g., correlated geometric Brownian motions or mean-reverting diffusions) and then the corresponding dynamics for the futures prices is obtained by substituting the expressions for $S(t)$ and $y(t)$ into the cost-of-carry relationship (6). Sometimes, the interest rate can be added as another fundamental factor, as in [11]. The cost-of-carry relationship (6) holds under any probability measure, so for the purposes of derivatives pricing, the risk-neutral dynamics of futures prices can be obtained from the risk-neutral dynamics of the fundamental factors.

The Seasonal Forward Curve Models

Seasonal forward curves are often observed in energy and agricultural markets. One attempt to model these has been made by Sorensen [14] and Lucia and Schwartz [10] who consider a deterministic seasonal component of the spot price, which subsequently enters the expression for the forward prices. However, seasonality in forward prices obtained in this way does not match the empirically observed seasonal patterns present in a forward curve, especially the observation that the forward price's seasonality

is a function of the contract maturity T and not so much of the current date t .

Forward prices of seasonal energy commodities such as natural gas and electricity are influenced by seasonal demand due to heating or air-conditioning; agricultural commodities are influenced by seasonal supply (harvest). These constraints result in positive seasonal premia attached to futures maturing in calendar months of high demand or low supply. The seasonal cost-of-carry model by Borovkova and Geman [2] incorporates such a seasonal premium within the framework of statistical arbitrage-like relationship.

Assume that the forward curve contains liquid maturities up to one year (12 months) or an integer number of years. The first fundamental factor of the seasonal cost-of-carry model is defined as *the geometric average of the observed forward prices at date t* :

$$\bar{F}(t) = \sqrt[N]{\prod_{T=1}^N F(t, T)} \quad (7)$$

where N is the most distant maturity. The average level of the forward curve $\bar{F}(t)$ is a robust quantity and a good indicator of the overall state of the forward market (more so than the volatile spot price). Note that, if $N = 12 \times k$ ($k = 1, 2, \dots$), then $\bar{F}(t)$ is a nonseasonal quantity, unlike a possibly seasonal spot price. Furthermore, the commodity spot price can be unreliable or even unavailable, so it is often not a good candidate to be the main fundamental factor driving the forward curve.

The seasonal premia $s(M)$, ($M = 1, \dots, 12$), less associated with calendar months, are defined as *the average premia, expressed in per cent, in futures expiring in the calendar month M with respect to the day- t average forward price $\bar{F}(t)$* . It is assumed to be deterministic and $\sum_{M=1}^{12} s(M) = 0$.

The *seasonal cost-of-carry model* describes the relationship between the prevailing forward price $\bar{F}(t)$ and the futures price $F(t, T)$:

$$F(t, T) = \bar{F}(t)e^{[s(T)-\gamma(t, T-t)](T-t)} \quad (8)$$

where the quantity $\gamma(t, T - t)$, defined by the relationship above, is called the *stochastic premium* at date t (as opposed to the deterministic seasonal premium $s(T)$), associated with the time to maturity $T - t$. Denoting $\tau = T - t$, the stochastic premium becomes $\gamma(t, \tau) = \gamma(t, T - t)$, which emphasizes

that γ is associated with the time to maturity τ rather than the maturity date T .

Therefore, futures maturing in a particular calendar month can be either at a premium or a discount relative to the average level of the forward curve. This is a periodic, that is, seasonal effect, which is associated with periods of high demand or low supply. The seasonal premium is the nonstochastic quantity $s(M)$, which can be consistently estimated from the historical data. The quantity $\gamma(t, \tau)$, on the other hand, is a stochastic process in t , indexed by the time to maturity τ , and summarizes all deviations of the actual observed futures prices from the anticipated futures prices given by $\bar{F}(t)e^{s(T)}$. It is called the *stochastic cost of carry*, or *stochastic premium devoid of seasonal premium*, for time to maturity τ . Factors influencing the function γ are, for example, levels of stocks, political news and events, or unusual weather conditions.

The seasonal cost-of-carry model (8) is related to the traditional cost-of-carry models such as the one in [3], but with the traditional convenience yield replaced by the stochastic premium $\gamma(t, \tau)$. This stochastic premium can be seen as the “relative convenience yield” (with respect to its average across all maturities), net of the scaled seasonal premium:

$$y(t, T) - \frac{1}{N} \sum_{M=1}^N y(t, M) = \gamma(t, \tau) - \frac{s(T)}{\tau} \quad (9)$$

where $y(t, T)$ is the traditional convenience yield.

The convergence property of the futures price to the spot price (1) provides the following expression for the spot price within the seasonal cost-of-carry

model:

$$S(t) = \bar{F}(t)e^{s(t)} \quad (10)$$

hence, if the spot price is not available in a particular market, the above relationship can be used to define a valuable proxy for the spot price.

The stochastic premium can be represented by a mean-reverting process, where the parameters of the process (such as the mean-reversion speed, level, and volatility) may differ per time to maturity τ . The entire term structure of $\gamma(t, \tau)$ can be driven by the same Brownian motion $W(t)$; more sources of uncertainty can be easily incorporated. The average forward price $\bar{F}(t)$ can be modeled by any appropriate diffusion or jump-diffusion process, uncorrelated to the term structure of $\{\gamma(t, \tau)\}_\tau$.

The seasonal premium and other model parameters can be estimated from the set of historical futures prices by the ordinary least squares method or a Kalman filter methodology. Figure 4 shows the estimated seasonal premia for UK natural gas, electricity, and heating oil futures. Our estimates are based on historical data sets of ICE futures prices from 2001 to 2008.

As expected, futures expiring in winter are at a premium with respect to the average price level, and summer futures at a discount. December gas futures are on average at a 28% premium and December electricity futures are at 15% premium. The seasonal premium for heating oil is generally smaller, and is at most 3%, which reflects a wider availability of storage and transportation for heating oil.

For longer forward curves (such as the one depicted in Figure 3), a significant slope (defining an overall backwardation or contango state) can be

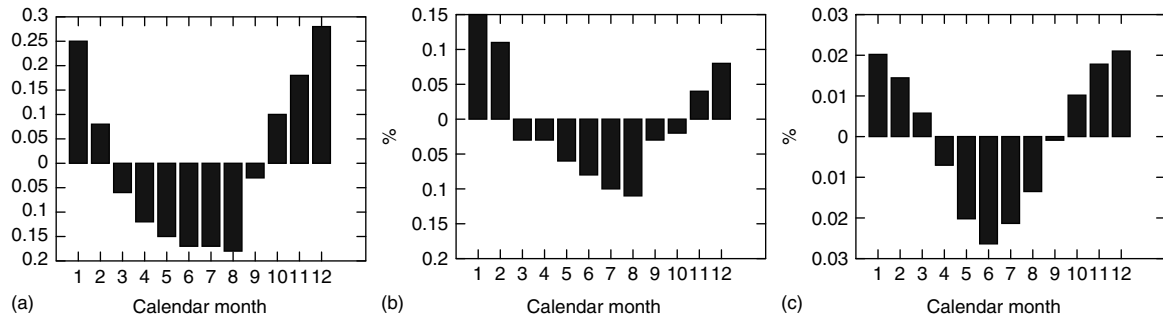

Figure 4 Natural gas, electricity, and heating oil seasonal premia. (a) Seasonal component, natural gas futures. (b) Seasonal forward premium, electricity futures. (c) Gasoil seasonal component

detected. In such cases, instead of defining the $\bar{F}(t)$ as the day- t level of the forward curve, we can approximate the overall shape of the log-forward curve on day t by a straight line fitted to all available forward log prices:

$$X_\tau(t) = X_0(t) + \alpha(t)\tau \quad (11)$$

where the parameters $\alpha(t)$ (slope) and $X_0(t)$ (intercept) are estimated on each day t by the ordinary least squares method. Note that equation (11) defines an affine function of the time to maturity. If the slope $\alpha(t)$ on day t is negative, then the forward curve is in overall backwardation, such as in Figure 3, where the seasonal premium is still clearly present. The positive $\alpha(t)$ defines the contango forward curve shape. If $\alpha(t)$ is not significantly different from zero, then we are in the situation of the initial seasonal cost-of-carry model, with the parameter $\bar{F}_0(t) = e^{X_0(t)}$ being exactly the geometric average of the forward curve $\bar{F}(t)$.

The seasonal premia $s(M)$ ($M = 1, \dots, 12$) are defined, as before, by the average premia in futures expiring in the calendar month M , but now with respect to the day- t overall shape of the forward curve, given by the exponent of equation (11). The *generalized seasonal cost-of-carry model* is given by

$$F(t, T) = \bar{F}_0(t)e^{\alpha(t)\tau + s(T) - \gamma(t, \tau)\tau}, \quad \tau = T - t \quad (12)$$

where $\gamma(t, \tau)$ is again the stochastic forward premium, defined by the relationship (12) above. This is a three-factor model. The slope $\alpha(t)$, the intercept $X_0(t)$, and the stochastic premium $\gamma(t, \tau)$ are the three fundamental factors. The factors $X_0(t)$ and $\alpha(t)$ have a well-known interpretation, closely related to the principal component analysis of the forward curve. They reflect the *level and slope* of the forward curve on date t and contain most of the forward curve's variability. The remaining stochastic variation of the forward curve, in particular its curvature, is summarized in the stochastic forward premia $\gamma(t, \tau)$. All three fundamental factors are pairwise uncorrelated.

The dynamics of the factor $X_0(t)$ can be a process mean reverting to a constant or an increasing level, or a geometric Brownian motion. Jumps can be incorporated into $X_0(t)$ as well. The slope $\alpha(t)$ and

the stochastic premium $\gamma(t, \tau)$ can be modeled as (uncorrelated) mean-reverting processes.

Specifying the factors' dynamics leads to the corresponding forward price dynamics *via* the relationship (12), which holds under any probability measure (statistical or risk neutral). Risk management applications, scenario simulations, and portfolio strategies involving spot and forward positions can be devised using the representation under the statistical probability measure. For purposes of derivatives pricing, the risk-neutral dynamics is of interest. Specifying such dynamics for the three fundamental factors implies the risk-neutral dynamics and distributions for the futures prices. With these in hand, derivatives such as futures options or calendar spread options can be easily valued by a Black–Scholes-like approach or by Monte Carlo simulations. Recall that, under the risk-neutral measure Q , futures prices are martingales, that is, their drift is identically zero. This results in a restriction on the model parameters under Q , similar to the HJM condition [7] on Treasury forward rates, or the conditions obtained by Amin *et al.* [1].

Conclusions

Building a well-functioning model for commodity forward curves is a challenging task owing to particular features of commodity markets and an inherent multidimensionality of the problem. Applications of commodity forward curve models include the generation of realistic forward curves for risk management and scenario simulations. Moreover, an appropriate model can be used for extending the observed forward curves beyond the most distant liquid maturity, a necessary task in the valuation of physical assets such as gas storage facilities or refineries. The formulation of the fundamental factors' risk-neutral dynamics provides a unifying framework for pricing derivatives, such as calendar spread options, that depend on the entire forward curve.

End Notes

^aAs a futures contract does not require an initial investment, under Q its price remains constant on average and there is no drift term representing the average growth on the investment.

^bIf these risk factors are obtained by the principal component analysis, they are usually interpreted as changes in the level, slope, and curvature of the forward curve.

Commodity Price Models

Arbitrage models of commodity prices are relative pricing devices. They allow market operators to evaluate commodity-linked securities in terms of *quoted* commodity prices or indices. Spark and crack spread options, multicommodity basket options, swing contracts, and collateralized commodity obligations are just a few examples of financial securities that can be priced (and thus hedged) using commodity models [17]. Moreover, the valuation of certain real assets may benefit from the use of these models. That is the case of long-term investments in natural resources, which can be interpreted as real (vs. financial) options written on the value of the corresponding commodity price(s) [37].

Models differ in the *primitives* from which prices of more complex positions can be derived and in the way the stochastic dynamics of these building blocks is described. As a consequence, model selection mainly depends on the level of development characterizing the market under consideration. For instance, oil markets are rather mature; they provide traders with a large quantity of reliable quotes for futures as well as vanilla options; these prices may thus be considered as model primitives. On the contrary, several electricity markets quote spot prices only, which then constitute candidate primitives for valuation purposes.

We begin by deriving the most important commodity valuation formula based on arbitrage considerations; then, we consider four major classes of commodity price models, each one gathering models sharing a common set of primitives; finally, we address a number of modeling issues underlying the design of risk management systems for commodity portfolios.

Net convenience revenue is defined as the sum of all benefits (e.g., saved costs of shortage, consumption value, and other side cash flows) minus the sum of all costs (e.g., storage expenses and replacement costs for perishable goods) stemming from physically holding a storable commodity over a period of time [8]. For the purpose of pricing forward contracts, which represent the simplest class of commodity derivatives, net convenience revenue must be computed net of the risk-free rate of interest on the currency of denomination representing the purely financial cost of funding the operation. This

computation results in a quantity referred to as *cost of carry*. The underlying argument goes as follows.

Current time is denoted by t . We consider a forward contract delivering a single unit of a commodity at a future time $T > t$ for a price $x(t)$. Although this price is determined at current time t , it represents a cash flow occurring at time T . It is assumed that holding the asset over the time interval $[t, T]$ leads to an overall benefit B and bears a total cost C , both quantities expressed in units of currency available at time T . A short forward position at time t leads to a time T pay off equal to $x(t) - S(T)$. At a first glance, one may think of hedging this cash flow by borrowing the present value of delivery price $x(t)$ and then buying the underlying asset at current price $S(t)$. However, this strategy generates the required cash flow $S(T) - x(t)$ *plus* an additional amount given by the net convenience revenue resulting from the asset holding. We then have to modify our trading strategy in a way to offset the resulting net convenience revenue. This can be done by borrowing funds equal to the present value of $B - C$. Table 1 illustrates the resulting *replicating strategy*, which is commonly referred to as *cash-and-carry*. V_f denotes the forward contract value and $P_T(t)$ is the discount factor representing the time t value of 1 unit of currency of denomination available at time T .

The net cash flow $V_\pi(T)$ resulting from this trading strategy at delivery is zero. Barring arbitrage opportunities, the time t value $V_\pi(t)$ of the resulting position must vanish as well. This fact leads to a formula for the commodity *forward (fair) value* V_f :

$$\begin{aligned} V_\pi(t) &= 0 \Leftrightarrow V_f(t) \\ &= S(t) - [x(t) + B - C] \times P_T(t) \end{aligned} \quad (1)$$

The corresponding time t *forward price* $f_T(t)$ is defined as the unique delivery price $x(t)$ negotiated at time t and making the value V_f of the forward contract equal to zero at the same time:

$$f_T(t) = x(t) : V_f(t) = 0 \quad (2)$$

Solving this equation with respect to the unknown delivery price $x(t)$ leads to a formula for the arbitrage-free forward price:

$$f_T(t) = \frac{S(t)}{P_T(t)} - (B - C) \quad (3)$$

Table 1 Replicating strategy for a commodity forward contract

	Position value at t	Value at T
1 short forward	$-V_f(t)$	$-S(T) + x(t)$
Borrowing \$	$-[x(t) + B] P_T(t)$	$-x(t) - B$
Lending \$	$+C \times P_T(t)$	$+C$
1 long asset	$+S(t)$	$+S(T) + B - C$
Portfolio π	$V_\pi(t) = -V_f(t) - [x(t) + B - C] \times P_T(t) + S(t)$	$V_\pi(T) = 0$

If side benefits and costs quote in terms of continuously compounded rates of appreciation β and depreciation χ respectively, then we may write the *spot-forward parity* (3) in the continuously compounded multiplicative form:

$$f_T(t) = \frac{S(t)}{P_T(t)} e^{-(\beta - \chi)[T - t]} \quad (4)$$

The difference $c := \beta - \chi$ defines the notion of *average spot convenience yield* per time unit. If r denotes the continuously compounded risk-free interest yield prevailing on average over the forward contract lifetime, then $f_T(t) = S(t) e^{[r - (\beta - \chi)][T - t]}$ and the factor $r - (\beta - \chi)$ represents the yield quoted *average cost of carry* per time unit.

Spot-forward parities (3) and (4) result from arbitrage considerations under the assumption that:

1. a spot price is quoted;
2. forward delivery occurs at a single fixed point in time;
3. the underlying asset is storable.

In contrast to hypothesis 1, some markets (e.g., oil) do not quote prices for spot delivery. In this case, we may either identify spot with the shortest maturity forward, or simply avoid considering spot prices and focus on forward curve models, whereby forward prices are model primitives and the spot is a derived quantity. As opposed to assumption 2, a few markets (e.g., electricity and shipping freight) quote forwards for delivery over a whole time period. A possible way out consists in finding implied forward prices compatible to the existing market quotes [28]. As far as assumption 3 is concerned, some commodities (e.g., electricity) cannot be stored. This fact prevents traders from performing a cash-and-carry strategy in the way described earlier, which may lead to denying the validity of the spot-forward parity. However, asset storability is not actually required to derive this relationship. One simply need be able to enter

a commitment whereby the asset is delivered on the future date T at the standing spot price $S(T)$. This is the case, for instance, of a trader owning the right to handle a production unit with available capacity on the date of delivery.

If any process between interest rate and convenience yield is stochastic, one has to rely on the general arbitrage pricing formula. This formula states that the fair value of a financial security is the risk-neutral expected value of the sum of all discounted future cash flows going to the holder. In a diffusion model setting, risk neutrality operatively translates into a price drift $\mu_S^*(t)$ that can equivalently be written either as an *instantaneous cost of carry* $r(t) - c(t)$ or as the historical price drift $\mu_S(t)$ plus the product between price volatility $\sigma_S(t)$ and a *market price of risk* process $\lambda(t)$. This latter can be estimated using methods proposed by Benth *et al.* [4] and Kolos and Ronn [29], among others.

In the case of a forward contract issued at time t and maturing at a future time $T > t$, the fair value at time $s : t \leq s \leq T$ reads as follows:

$$V_f(s) = \mathbb{E}_s^{\mathbb{P}^*} \left(e^{-\int_s^T r(u) du} (S(T) - x(t)) \right) \quad (5)$$

where $\mathbb{P}^*$ denotes the risk-neutral probability, and $r = (r(u), t \leq u)$ is the interest rate process. Substituting this quantity into the zero-value condition (2) and solving for the delivery price leads to a *general spot-forward parity*:

$$f_T(t) = \frac{\mathbb{E}_t^{\mathbb{P}^*} \left(e^{-\int_t^T r(s) ds} S(T) \right)}{P_T(t)} \quad (6)$$

We note that the underlying convenience revenue implicitly appears via the risk-neutral drift of spot price dynamics, that is, $\mu_S^*(t) = r(t) - c(t)$. We refer to $c(t)$ as the *instantaneous spot convenience yield* associated to commodity S . A more explicit expression is derived in [25] under the assumption

of a deterministic covariance between spot price and the exponentially integrated convenience yield processes.

Gibson and Schwartz [21] propose a model where commodity prices evolve through a continuous diffusion process driven by two factors: one factor is idiosyncratic to spot price returns; the other affects price evolution through the instantaneous convenience yield process. The resulting $\mathbb{P}^*$ -dynamics read as follows:

$$dS(t) = [r - c(t)]S(t)dt + \sigma_S S(t)dW_S(t) \quad (7)$$

$$dc(t) = \kappa[\alpha^* - c(t)]dt + \sigma_c dW_c(t) \quad (8)$$

where σ_S (respectively, σ_c) represents the spot price return (respectively, instantaneous convenience yield) volatility coefficient κ denotes the mean reversion frequency of convenience yield; $\alpha^* = \alpha + \sigma_c \lambda \kappa^{-1}$ (respectively, α) indicates the risk-neutral (respectively, historical) long-term convenience yield level; and the two $\mathbb{P}^*$ -Brownian motions W_S and W_c are assumed to be correlated with a coefficient ρ . These dynamics are assumed to start at initial values $S(t_0)$ and $c(t_0)$. The model represents a prototype for the *spot-convenience yield model* class (SC models). Bjerk Sund (1991, unpublished manuscript) and Jamshidian and Fein [26] show that forward prices in this model are exponentially affine functions of the pair $(\ln S(t), c(t))$. This feature is shared by most SC models, a fact leading Björk and Landén [6] to pursue a systematic study of affine models for commodity prices in the general setting of jump-diffusions (see **Affine Models** for details on affine models in the context of interest rates). SC models have been extensively studied in a number of papers, such as [10, 16, 30, 33, 37, 38], among others. Extensions to jump-diffusions can be found in [12] and [22].

SC models are intuitive in terms of economic interpretation and deliver analytically tractable expressions. However, they experience all consequences stemming from the highly reduced observability of their primitives. First, commodity markets do not quote instantaneous convenience yields. Consequently, filtering techniques (e.g., Kalman) are required to estimate the corresponding process. However, these procedures may deliver an unstable assessment of model parameters, a fact that can undermine the significance of hedging prescriptions resulting

from a fitted model. Second, fitting quoted forward curves or term structures of volatility and correlation requires the use of calibration procedures whose effectiveness and numerical stability must be evaluated case by case. Once more, the attention of the modeler is drawn on the nature of the primitives involved in the modeling process. These considerations led a few authors to propose the *forward model* class (FD models) as a viable alternative to SC models.

Jamshidian [24] directly assigns *futures* price $F_T(t)$ dynamics under the risk-neutral probability $\mathbb{P}^*$ as

$$\frac{dF_T(t)}{F_T(t)} = \Sigma_T(t) d\mathbf{W}(t) \quad (9)$$

where the initial condition $(F_T(t_0), T \geq t_0)$ is represented by the currently quoted forward price curve and $\mathbf{W}$ is an n -dimensional standard Brownian motion. As theory requires, these processes are all $\mathbb{P}^*$ -martingales, that is, they exhibit no drift [14]. If interest rates are deterministic, model (9) can be used to describe forward price dynamics as well. This is particularly important in view of the observation that interest rate volatility is usually dominated by commodity price volatility and thus the time value of money can assumed to be nonrandom in this kind of model [37]. Any particular instance of this class results from assigning a value to each of the following three quantities:

1. a futures/forward curve quoted at time t_0 ;
2. a number n of statistically independent driving factors;
3. a volatility structure $(\Sigma_T(t), t_0 \leq t \leq T)$.

FD models have been studied by Cortazar and Schwartz [11] and Audet *et al.* [2], among others. In particular, Andersen [1] illustrates a number of alternative modeling frameworks and examines their performance in option calibration.

The main benefit from using FD models is that primitives are observable quantities, possibly up to a deterministic transformation of market price data. Moreover, FD models are very intuitive and flexible from a trader's perspective. For instance, they easily allow the user to identify noise terms with a number of forward curve deformations resulting from a statistical analysis of historical market moves. As a result, one obtains a picture of the number of significant noise driving terms as well as the way

they impact on the various sections of the forward curve (see [39], among others).

However, spot dynamics implied by FD models *via* the self-explaining assignment $S(t) := F_t(t)$ need not be Markovian processes. Jamshidian [24] first derives conditions on the volatility structure, ensuring that the resulting spot price dynamics is Markovian. Unfortunately, this and subsequent results pursued within one-factor Heath–Jarrow–Morton interest rate setting cannot be applied to SC models that involve two-factor Markovian processes. Using the Cheyette’s technique developed for multidimensional HJM interest rates models, Andersen [1] disentangles abstract Markovian factors underlying forward price dynamics. Alternatively, Roncoroni and Id Brik [36] pursue a systematic study on the direct correspondence between SC models and FD models.

A third class of models has been proposed by Miltersen and Schwartz [32]. These authors consider the notion of *instantaneous forward convenience yield* $c_T(t)$ as implicitly defined through:

$$F_T(t) = S(t) e^{\int_t^T c_s(t) ds} \quad (10)$$

for all $T \geq t$. It can be shown that the process $c_t(t)$ is actually the instantaneous convenience yield defined as the formal “instantaneous dividend rate” process $c(t)$ entering the risk-neutral drift in expression (7). More precisely, Bjork and Landen [6] show that

$$c_T(t) = \mathbb{E}_t^{\mathbb{P}^*}(c(T)) + \frac{\text{Cov}_t^{\mathbb{P}^*}\left(e^{-\int_t^T r(u) du} S(T), c(T)\right)}{\mathbb{E}_t^{\mathbb{P}^*}\left(e^{-\int_t^T r(u) du} S(T)\right)} \quad (11)$$

from which we deduce that $c_t(t) = c(t)$.

Although formula (10) defines $c_T(t)$ in terms of forward and spot prices, for modeling purposes it is actually used the other way around: processes S and c_T are defined as primitives for a set of maturities T ; then forward prices are derived using expression (10) and drift restrictions are calculated on the c_T dynamics. This methodology defines the *forward convenience yield* model class (FC models). An interesting application of this setting is represented by the calibration procedure developed in [31].

Compared to both SC and FD models, this setting has the advantage of clearly exhibiting the contribution of spot price and convenience revenue to the formation of a forward price. FC models suffer from similar drawbacks as those affecting SC models: spot prices may be unavailable in the market under consideration; also, (instantaneous forward) convenience yields are rather difficult to imply from market quotes. In particular, differentiating a term structure of forward prices resulting from fitting observed market quotes may generate a curve exhibiting pronounced spikes because of the instability of the differential operator.

A final modeling framework is perhaps the simplest and most popular one. The idea is to focus on the fine properties of a particular class of commodity spot prices without assuming any stochastic structure about the underlying convenience yield dynamics. This restrictive assumption is partly offset by the flexibility introduced upon selecting an appropriate spot price process for modeling and pricing purposes. Spot models for energy price dynamics include [1, 3, 7, 9, 13, 15, 18, 20, 23, 27, 34, 35], among others. Eydeland and Wolyniec [17] and Fusai and Roncoroni [19] report a large number of examples and references about one-factor commodity price models.

At the time of writing, there seems to be no general consensus on a benchmark setting for pricing commodity-linked derivatives. As a consequence of the arguments illustrated here, we may suggest for the modeler to focus on primitives, structural elements, and driving noise terms.

1. *Primitives.* They should be selected within the set of market quantities for which reliable data are available. In our view, these may involve an appropriate combination of spot, forward, and swap prices or indices according to considerations of representativeness and liquidity. For instance, a market model for electricity or shipping freight indices may build on average prices as introduced in [5], while the general Markovian FD models framework may provide a model generator more suitable for gas and oil markets.
2. *Structural elements.* A proper form for price drift, volatility, and jump components, if any, should be identified using statistical analysis of historical data and then fitted to observed prices. One may perform a nonparametric estimation of

these characteristics and then define an appropriate family of functions reproducing the features displayed by the estimated graphs. Besides representativeness, structural elements ought to be selected in such a way that the resulting model is stable under statistical estimation, a property that goes with the reliability of all valuation assessments and hedging prescriptions stemming from using the model in practice.

3. *Driving noise terms.* Number and nature of underlying noise terms should be assessed on the basis of historical price analysis (e.g., examination of the trajectorial properties of price paths, principal components analysis) and jump filtering. For instance, a strong deviation of market price returns measured over short-time-lagged data should be interpreted as a sign that prices experience shocks of jump nature. Also, slowly decreasing eigenvalues of the historical covariance matrix of forward price returns are an indication of the significance of asynchronous movements affecting forward curve dynamics.

Oil Market

The development of the internal combustion engine one century ago was the principal cause of the development of the oil market. In the 1950s, oil became more important than coal. Since then its importance has kept increasing, though it has been recently largely displaced by natural gas for heating and electricity generation. The rapid economic growth of China and of India has increased the world demand for oil. Currently, demand exceeds 90 billion barrels a day, stretching the global production capacity.

Bringing new oil fields to production requires typically several years and very large investments. The economic hurdles are compounded by environmental worries and by the unstable market structure of oil. Market instability is due to the low short-term elasticity of oil consumption to price changes. The large price fluctuations implied by the low elasticity of oil prices being related to trends in world economy carry a substantial risk premium that increases the cost of capital for oil projects. Over longer time periods, high prices discourage demand and increase production. Lower prices have the opposite effects. This leads to substantial mean reversion in oil prices over longer intervals. Over the long run, real oil prices have been mostly declining in real terms, with the exception of 1973–1981 and the current uptrend since 1998 (see Figure 1). Demand has been steadily increasing and it is projected that it will continue to grow (Figure 2). The concentration of oil reserves in the Middle East (Figure 3) suggests that members of the Organization of Petroleum Exporting Countries (OPEC) will cover a greater share of world production in the future (Figure 4). The very low marginal cost of production of most of OPEC oil acts as an additional deterrent to the investment necessary for the development of alternative resources.

Crude Oil

The price of crude oil varies with the ease of refining it. Lower density oil with lower sulfur content is more easily processed. The market for crude oil is based on the two benchmarks of Brent and West Texas Intermediate (WTI) oil. Changes in these benchmarks show little day-to-day correlation with changes in prices of Middle Eastern oil. It is likely that, owing

to the increasing oil flow to Asia, a new benchmark will soon emerge.

The spot market for oil is dwarfed by the futures market that currently has volumes about 15 times larger than the market for physical oil. Oil swaps bridge gaps between short-term maturities and allow also for trading over very long maturities. Historically, the WTI price was slightly higher than the Brent price, reflecting the fact that the difference in oil price across the Atlantic was centered around the marginal cost of shipping oil westward. The emergence of China as the largest oil importer has led recently to frequent spread reversals. Local imbalances are now more random because of the growing importance of the eastward flow of Middle Eastern oil.

Futures

Futures contracts require the delivery of oil at a later date. They are standardized for quantity and quality, they are traded in exchanges, and their delivery price is adjusted daily to reflect changes in value and limit credit risk (mark to market). Margin requirements ensure the funds necessary for marking to market [1].

Traders are commonly classified as hedgers, market makers, or speculators. Hedgers want to offset price risk. They regard these contracts as insurance contracts. They are willing to pay a premium to reduce their risk. Market makers provide liquidity and hope to gain from temporary imbalances of supply and demand. Speculators take a position based on their view of price trends, with no specific interest to trade physical oil.

Most futures trade for maturities up to five years, though contracts up to eight years exist. Over-the-counter trading is active up to 10 years. Mean reversion reduces the correlation of price changes at maturities far apart and limits the relevance of current shocks for far delivery. Because of low correlation, diversification across maturities may achieve significant risk reduction. Diversifying across qualities, or even across most commodities, leads to much smaller risk reduction because the price of most commodities is highly correlated with the price of oil for the same maturity.

Most futures contracts are settled by entering the opposite trade. This allows hedgers more flexibility on delivery time, place, and quality. The difference

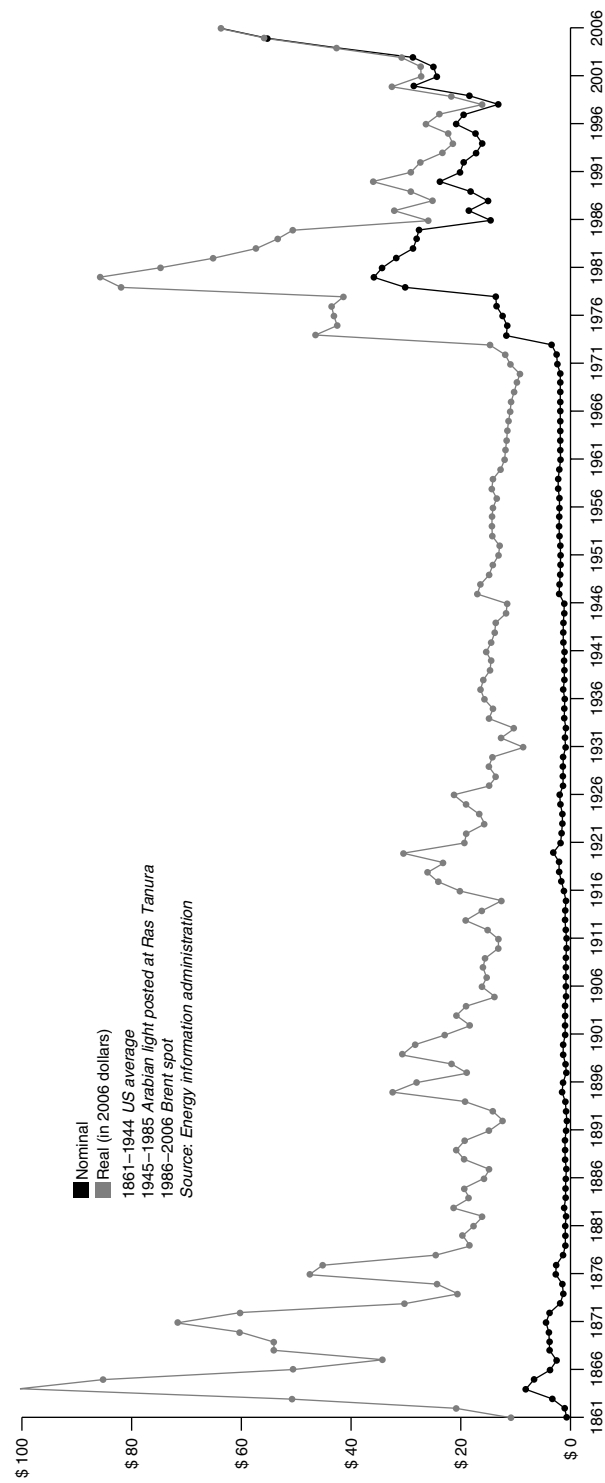

Figure 1 Real and nominal oil prices, 1861–2004

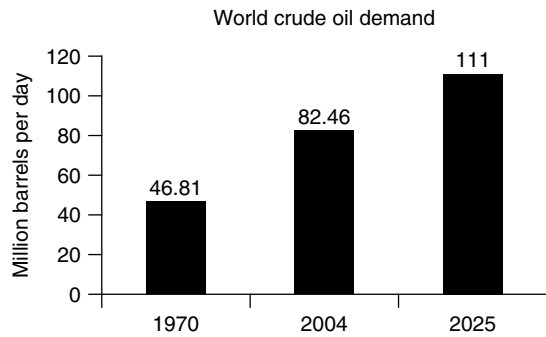

Figure 2 World oil demand

between the spot and the futures price is called *basis*. Because hedgers, after closing their future position, need to trade in the physical market, their final result will depend not only on the change in value of their futures, but also on the change of basis. That is known as *basis risk*.

Crude Oil Curve

The crude oil curve shows the price of oil for delivery at different dates. Its shape changes through time, from upward (contango) to downward (backwardation) sloping, occasionally with a hump. The shape of

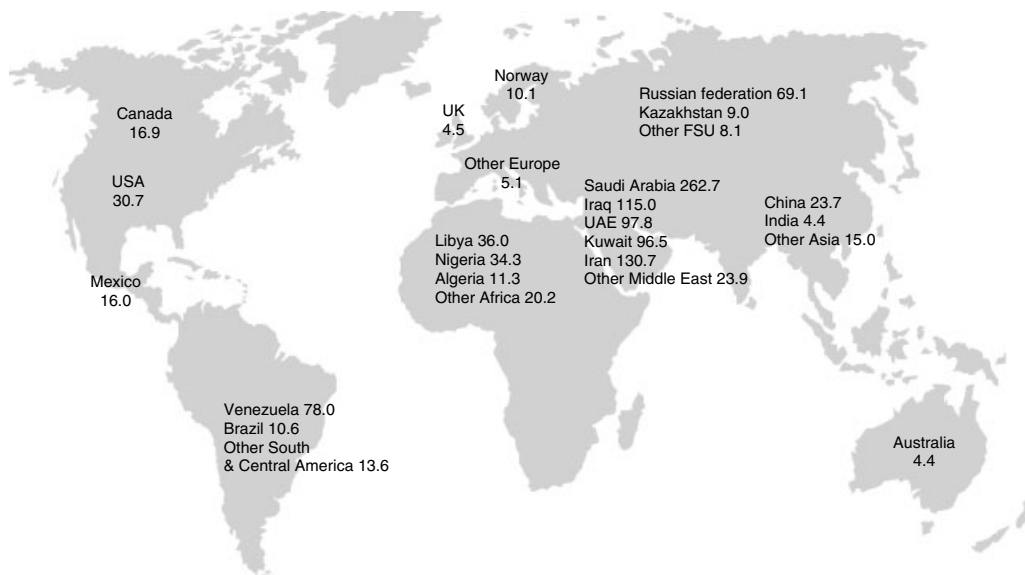

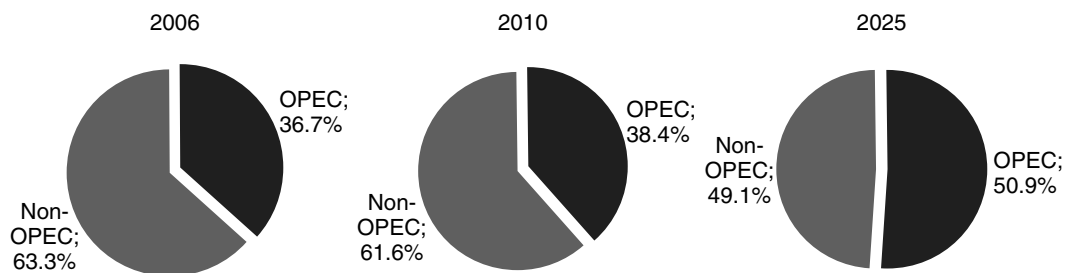

Figure 3 World oil reserves in billions of barrels, 2005

Source: BP Statistical Review

Figure 4 Market share of OPEC and other countries

the crude oil curve is influenced by the risk-free rate, the storage cost of oil, and inventory levels. When inventories are plentiful, investors are willing to hold them because the oil curve is typically upward sloping. The cost of financing and storing oil determines then the futures price in relation to the spot price. When the crude oil curve is downward sloping, the willingness of investors to hold oil is limited. Only investors who worry about the possibility that disruptions in supply may interfere with timely delivery are then willing to hold a physical inventory. The implicit cost of holding expensive oil that may only be delivered with certainty at a loss through the sale of futures contract is known as *convenience yield*. It represents the marginal benefit that investors assign to the flexible availability of oil relative to term delivery. It follows that convenience yield is negatively related to the slope of the crude oil curve. This traditional relationship has been challenged by the influx of financial institutions into the crude oil market since 2004. Moreover, oil tankers ensure that supply is very predictable for the next ninety days, while greater uncertainty dominates longer maturities.

Crack Spread

All the crude oil has to be processed in refineries. Refiners buy crude and sell refined products: gasoline,

diesel, heating oil. The difference between the price of a barrel of oil and the price of its refined components is known as *crack spread*. It represents the refiners' revenue for processing oil. It depends on the spare refining capacity available and the conditions prevailing in the markets for crude and refined products [2].

Commodities and Numéraire

In the last decade, there has been considerable interest in the commodities world, in energy, in particular, as evidenced by the number of press editorials that are being published on the subject. Commodity prices have been experiencing unprecedented moves in the last few years and there is no sign of change at the date of writing (January 2009). Demand for metals, energy, and cereals from Brazil and Russia, two of the fastest growing economies, has undoubtedly increased the volatility across all commodity classes. As an example, between 2001 and 2005, China's demand for copper, aluminum, and iron increased by 78%, 85%, and 92%, respectively.

Energy prices, for example, those of crude oil and coal, have witnessed a very high volatility over the last two years, under the combined effect of a greater public awareness of the exhaustible nature of fossil energy, the massive arrival of new players into commodities, and the current looming depression worldwide. The West Texas Intermediate (WTI) crude oil, that had undergone a respite in price increase during the year 2006, resumed in 2007 its irresistible ascent to go over the symbolic threshold of \$100 per barrel in early 2008. It went above \$140 per barrel in June and July, resulting in prices multiplying by more than 500% in less than four years, with—among other reasons—supply disruptions in Nigeria, a structural decline in production in Mexico and in other countries like the United Kingdom and the United States. Subsequently, crude oil prices decreased by more than \$100 between July and November 2008, another move never observed previously. This “spike”, unique in the history of oil markets, took place a year after the start of the subprime crisis and an explanation is difficult, at least, for the remarkable upward move. Call options on crude oil with strikes of \$100 or more were the subject of great surprise when they appeared in New York in summer 2006. By May 2008, there were 21 000 outstanding contracts for the NYMEX December 2008 call options with a strike of \$200 per barrel. In parallel, put options for the same maturity of December 2008 and a strike of \$100 traded at \$1.84 in July 2008; when they settled on November 17, 2008, crude oil prices were at \$54/bbl

and the buyers of the puts realized a net return of 2200%!

Commodities and Numéraire: Some Qualitative Aspects

Since commodities are essentially denominated in dollars, the weakness of the “numéraire”^a currency, at least until September 2008, has often been cited as a major cause for the rise of commodity prices. Still, in constant dollars, average crude oil prices rose by 124% over the period 2002–2006; and the increase up to July 2008 was even steeper. The entire WTI crude forward curve was trading over the level of \$105 with a backwardated shape in July 2008. Since the oil price more than halved the level of the forward curve changed to lower values and its shape went to a steep contango, with medium-term forward prices being higher than the first nearby price by more than \$15. And in the oil market, the contango shape has essentially been associated with a situation of crisis, as during at the time of the First Gulf War or after September 11, 2001 (Figure 1).

The same volatile market conditions across the spectrum of the three commodity classes—energy, metals, and agriculturals—are unlikely to drastically improve in the near future, with land itself becoming rare and water insufficient, disruptions occurring (like in 2008 in South African mines that represent, in particular, 80% of the world platinum production) because of electricity shortages, geopolitical issues in a number of countries producing commodities, and the world population growth. We can observe that these elements illuminate an interesting property, namely, that the three commodity subasset classes are increasingly *correlated*, a property that we can certainly view as novel in the commodity markets. Hence, energy companies like agri-food firms, bankers, and private equity funds, have all moved forward in the acquisition of new physical assets such as power plants, gas storage facilities, aluminum smelters, or grain elevators.

Looking back into the past, one should keep in mind that the history of commodities has been filled with booms, busts, seasonal volatility, weather events, geopolitical tensions, and occasional attempts to “corner” the market, features that were reasonably acting as a deterrent for new entrants. Moreover, the physical constraints of delivery and storage make spot

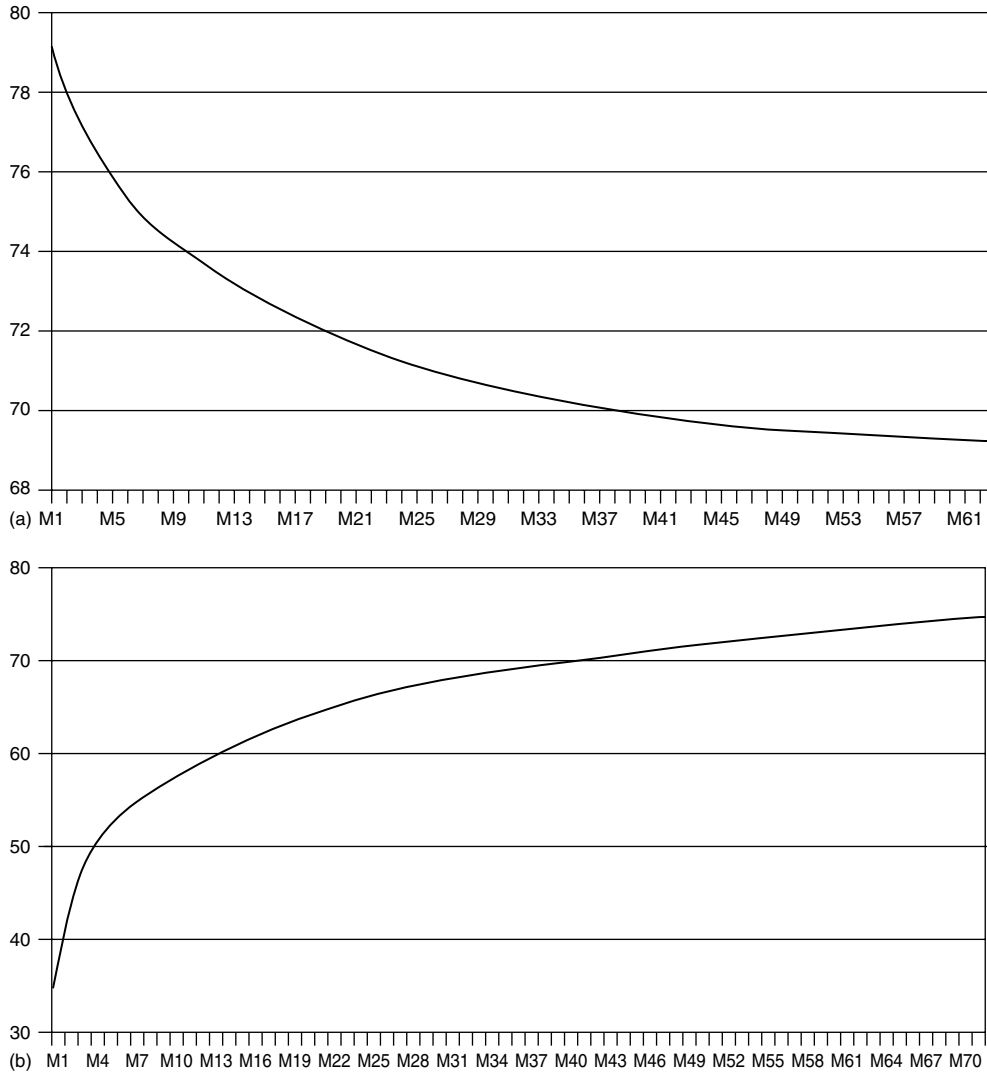

Figure 1 (a) Oil futures price curve (September 14, 2007); (b) Crude oil futures price curve (January 14, 2009)

commodity trading difficult or impossible; transactions on commodity futures exchanges can only be performed through a broker who is a member of the exchange (hence, the remarkable success of the recently introduced exchange-traded futures (ETFs)), that are accessible to individual investors. All market participants are increasingly aware of the fact that volatility swings reflect not only supply and demand concerns but also that these markets are sometimes dominated by large players, often opaque, and always directed by the long lead time between a production

decision and its actual viability. Trading volumes have also fluctuated widely over time: during the high inflation era of the 1970s, commodity futures trading exploded and the real estate sector boomed since bonds and stocks were generating a real return close to zero for over a decade. The commodity boom at the end of the 1970s can be identified with the crash in 1980 of precious metals prices, when the famous squeeze of the silver market by the Hunt Brothers (who were holding at some point an estimated 50% of the global deliverable supply of silver)

failed. Afterwards there was a long period, nearly 20 years, of stagnation in commodity prices that some experts attribute to supply fundamentals and low inflation, which lasted until the early 2000s. The present effects of the worldwide recession, together with the awareness that at any time the amount of every exhaustible commodity is *bounded*, tend to pull analysts' expectations in opposite directions.

Returning to the analysis of the numéraire effect, we plotted the trajectories over the period 2000–2008 of crude oil (Figure 2), copper (Figure 3), and gold prices (Figure 4) with respect to two “currency numéraires”, namely, the dollar and the euro; and the CRB (Commodity Research Bureau) index, which has been perceived for a long time in the United States as a very good proxy for inflation. For the

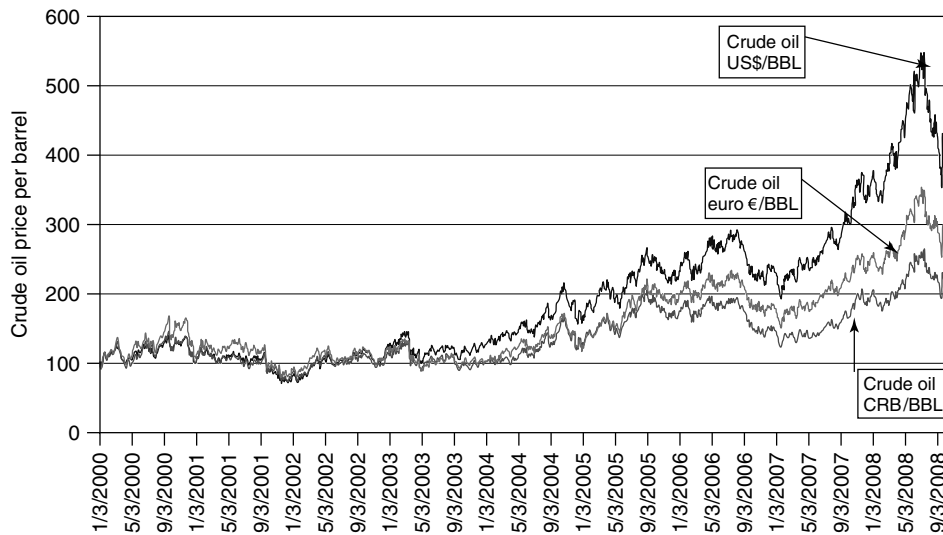

Figure 2 Crude oil relative prices

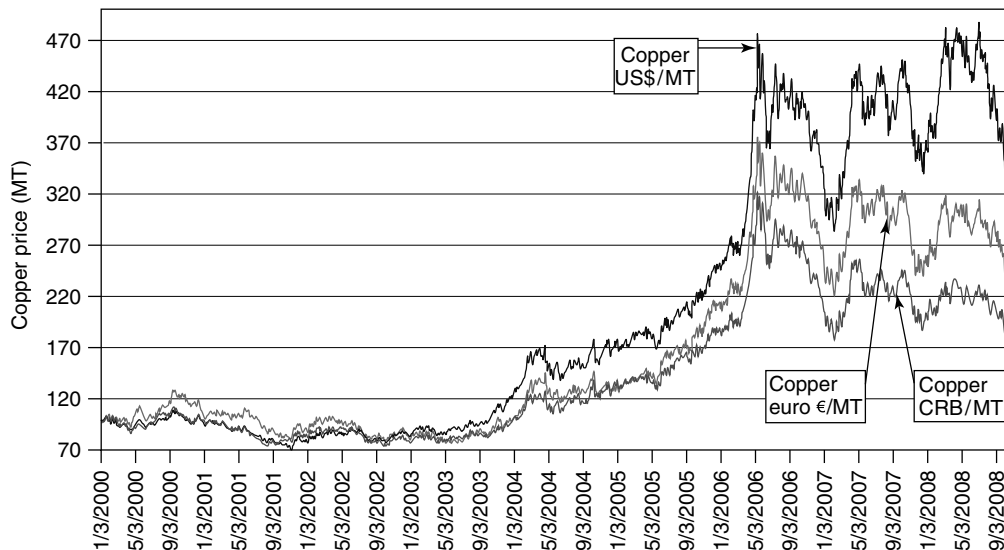

Figure 3 Copper relative prices

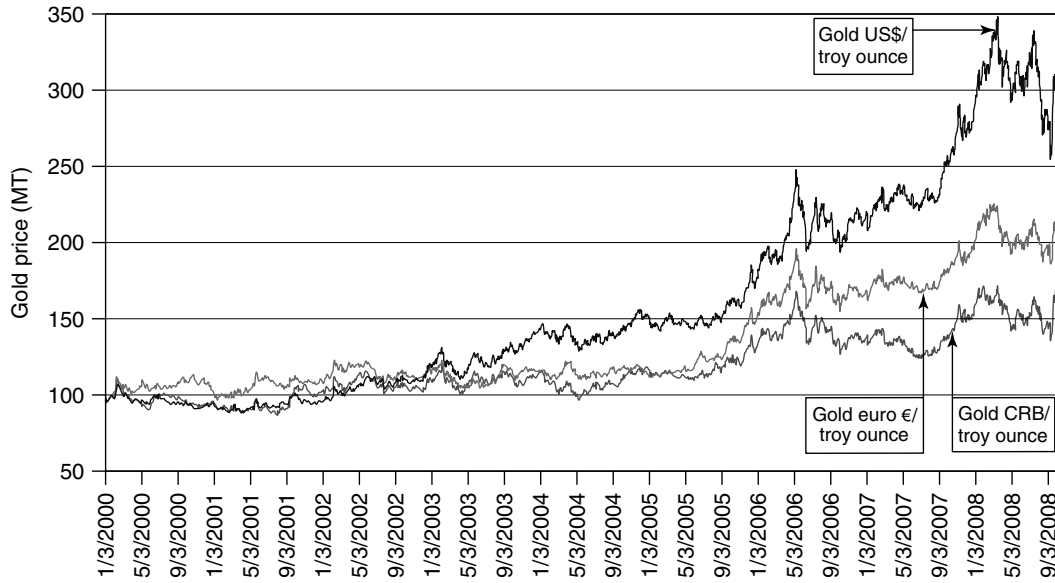

Figure 4 Gold relative prices

sake of comparison, we have normalized all relative prices to have a value of 100 at the starting date of analysis.

We observe that for both oil and copper, the change of numéraire has a remarkably little impact on the shape of the three trajectories, indicating that major effects such as supply and demand or the massive arrival of index funds and new market participants are the ones driving the commodity price changes.

Interestingly, the same property holds in the case of gold, namely, the absence of sensitivity of the trajectory shape to the numéraire currency or index. This is consistent with the fact that—for the current period at least—gold has lost its status of a special currency since its price has been falling sharply together with all commodity prices.

Commodities and Numéraire: Some Quantitative Aspects

Brief Reminders

A large and fascinating literature has established that the assumptions of no arbitrage, constant interest rates, and a general semimartingale for the stock price S lead to show the existence of a probability measure

Q such that the process $(S(t)e^{-rt})$ is a Q martingale. It is worth noting that this discounted price $S(t)e^{-rt}$ is nothing but the price of S with respect to the money market account numéraire M , where $M(0) = 1$ and $M(t) = e^{rt}$. As for the martingale representation, it brings a windfall of beautiful properties, including an alternative proof of the Black and Scholes [1] formula, as well as an essentially simple valuation of path-dependent options such as barrier, lookback, or Asian.

When moving to stochastic interest rates, M is not a valuable numéraire for pricing of contingent claims maturing at date T since it is not any more a “riskless asset” relative to date T . Instead, as shown in [4], the proper numéraire^b becomes the default-free zero-coupon bond B^T maturing at date T , that satisfies $B^T(T) = 1$. Moreover, the price of the risky stock S with respect to numéraire B^T is defined as $f^T(t) = S(t)/B^T(t)$ and has two fundamental properties:

- It represents the forward price of S , and in commodity markets, forward contracts are the central instruments.
- It is a martingale with respect to Q_T , the T -forward-adjusted probability measure, and hence offers an easy extension to stochastic interest rates of the Black and Scholes, Merton [1, 15], and other option pricing formulas.

From Stocks and Bonds to Commodities

Our view when turning to commodities is multifold and, in summary, is as follows:

1. Introducing stochastic *versus* constant interest rates when trading commodities (forwards/futures or options) is not a big gain in precision since interest rate moves are essentially quite small compared to commodity price moves and the recent period has been more extreme than ever in this direction.
2. This being stated, introducing stochastic interest rates is not a difficult matter since the most traded instruments in the world of commodities are the forward contracts whose prices, as mentioned before, are martingales under the “right” pricing measure, namely, the T -forward-adjusted probability measure. For futures contracts,^c the situation is different because of the margin calls (see [8] for a discussion in the case of non-storable commodities).
3. Turning now to a very different issue, which is the relevance of interest rates arbitrage models for commodities as discussed in the seminal paper [11] (see also **Heath–Jarrow–Morton Approach**), our view is that the benefit is limited. In fact, the large literature that transposed arbitrage models of interest rates may be misleading: default-free bonds (and even less so, interest rates) are very different from commodities. The world of commodities is characterized by possible squeezes, sudden lack of liquidity, and insufficient transparency, which make the assumption of no arbitrage (let alone market completeness and unicity of the risk-adjusted measure Q) essentially invalid [16].
4. The convenience yield y and the cost-of-carry relationship. The formula

$$f^T(t) = S(t)e^{(r-y)(T-t)} \quad (1)$$

introduced in the *Theory of Storage* by Keynes [13], did make sense in the minds of the famous economists Kaldor (1939) and Working (1949) because the convenience yield y —net of storage costs if defined as above—translates the preference for the ownership of the physical commodity over a forward contract as well as many other effects and market frictions, hence mitigating the importance of the no-arbitrage argument.

In the case of electricity, a nonstorable commodity, the existence of a commodity yield and the spot-forward relationship collapse together [3, 10]) as evidenced, for instance, by the abrupt convergence of the forward price $f^T(t)$ to the spot price at date T even in markets like the Nordpool, where a significant fraction of electricity is hydro [5]. The same holds for agriculturals with distant maturities because of their finite lifetime.

5. To avoid the doubtful arguments consisting in deriving the whole forward curve evolution from the spot price dynamics ($S(t)$), [2], also (see **Commodity Forward Curve Modeling**), when analyzing the risk management of a book of forward contracts (long or short, with different maturities), propose an original model consisting in replacing the spot price as the first state variable as in [9], by the average value $\bar{f}(t)$ of all liquid monthly forward contracts maturing before date H , and H a multiple of 12 to properly incorporate the seasonality in the case of natural gas and agricultural commodities ([7] for the case of soybeans).

Now $\bar{f}(t)$, the “backbone” of the forward curve—itsself the most fundamental tool when trading any commodity—becomes the numéraire with respect to which all forward prices are written as

$$f^T(t) = \bar{f}(t) \exp[s(T) - (T-t)\gamma(t, T)] \quad (2)$$

where

- a) $s(T)$ is the deterministic component of the relative cost-of-carry accounting for seasonality if it exists, expressed as an absolute quantity (for instance, the month of January effect).
- b) $\gamma(t, T)$ is the *rate of cost of carry* (including financing, convenience yield, and storage cost) relative to $\bar{f}$, assumed to be stochastic in t and deterministic in T (the latter assumption being possible relaxed).

Note that the relationship between $\bar{f}$ and f^T holds by definition of $\bar{f}$ and $\gamma(t, T)$ rather than by arbitrage arguments. Borovkova *et al.* (2006) show the validity of the model using data relative to seasonal (natural gas) and nonseasonal

(crude oil) commodities, and exhibit the property that the volatility $\gamma(t, T)$ decreases in T , an interesting extension of the Samuelson effect.

Lastly, the use of $\bar{f}$ as the relevant numéraire when trading a book of forward contracts can naturally be extended to electricity, a commodity for which we have already mentioned that the spot-forward relationship is not quite appropriate.

6. When turning to options on commodities, our main comments are as follows:
 - a) There should be a clear consistency between the two fundamental classes of derivatives, forwards, and options, and the measure $\mathcal{Q}$ (assuming its unicity) has to be derived from the forward curve where the liquidity is located.
 - b) Most financial options sold in the commodity world are backed by the physical optionalities attached to the ownership of physical assets such as a gas storage facility or a gas-fired power plant [5]. Hence, the valuation of these options is not tied to a particular model (a desirable feature after the catastrophic meltdown of the credit risk market), but rather to the “real” value of the externalized optionality.
 - c) Because of property b, many financial options on commodities are options to exchange a commodity S_1 for a commodity S_2 (for instance, crude oil for kerosene) or spread options. The natural numéraire is then S_1 and the relevant underlying the relative price S_2/S_1 , outside any assumption on interest rates. Note that Margrabe [14] (see **Margrabe Formula**) used the numéraire terminology in his remarkable paper, without introducing the associated change of measure; the latter would have made unnecessary the assumption of constant interest rates, as shown in [6].
7. Lastly, a worthwhile observation relative to the subject of commodities and numéraire is the following: let us consider the situation of a position held by an energy company based, for instance, in the United Kingdom, whose equity and profits are denominated in sterling pounds. Its portfolio typically contains crude oil, natural gas, electricity, coal, physical assets, and spot and derivatives contracts with counterparties based

in the United Kingdom, Norway, Germany, and Switzerland. In order to avoid, in a first stage, an array of currency risk, (Norwegian krone, Euro, *etc.*) and minimize the cost of risk management while exploiting the correlations between the various commodities when denominated in a single currency (US dollar for instance), one may decide to use the price X of a barrel of Brent crude oil, dollar-denominated, as the numéraire. Using affine relationships (e.g., indexation of natural gas to crude oil in Germany and other countries of continental Europe), correlations or co-integrations between the various energy commodity prices, the portfolio will be risk managed over time in terms of long and short positions with respect to crude oil. In the second stage, the “missing” components (orthogonal to crude oil) in the various other energy commodities will be accounted for; and in the third stage, the different currencies will be incorporated in the picture.

Conclusion

In a mature Walrasian economy [17], the general equilibrium output is enhanced by the optimal selection of the components of a multicommodity numéraire, according to the decisions of borrowers and lenders. The commodity evaluations that then emerge from transactions are accomplished by requiring that money in circulation be representative of this numéraire. This multicommodity numéraire is welfare optimal and should then constitute the real reserves of the monetary system.

End Notes

^aThe numéraire is the money unit of measure within an abstract economic model in which there is not necessarily actual money or currency. From a mathematical standpoint, it is a stochastic process, $X(t)$; where $X(t)$ is strictly positive almost surely at any date t and represents a self-financing portfolio.

^bNote that Jarrow [12] was the first one to introduce stochastic interest rates in option pricing and deliver the pricing formulas in the case of options on commodities and Gaussian interest rates. Jamshidian (1989) kept the

Gaussian interest rate setting to compute the prices of options on bonds. Geman [4] introduced the zero-coupon bond B^T as the new numéraire and showed that the introduction of the T -forward-adjusted probability measure Q_T does not require any assumption on the interest rate dynamics.

^cNote that if interest rates are nonstochastic, forward and futures prices are equal (in absence of credit risk), $Q = Q_T$, and the martingale property holds for both instruments under Q .

Swing Options

Unlike paper assets, trading in physical commodities often takes place over time and therefore involves volume as a second key state variable. Often, consumption rates of the commodity are unpredictable and make fixed delivery amounts uneconomic. To mitigate such *volume risk*, a swing contract gives the buyer the opportunity to manage fluctuating commodity demand levels in exchange for a fixed upfront fee. By exercising his or her swing up/down rights, the buyer can dynamically match supply and demand levels while hedging his or her costs. Swing options are widely offered by market makers and used extensively by major energy companies, especially in electricity and fossil fuel markets. Contracts with swing features are available as stand-alone financial tools; they can also be found embedded within structured physical transactions.

Definition and Use

A typical definition of a swing option is as follows. At times $n = 1, 2, \dots, N$ the buyer is to receive a *baseload* amount $\bar{K}$ of the commodity paying the strike price $\bar{P}$. In addition, over the life of the contract, the buyer has $N_c \leq N$ swing rights to temporarily vary these deliveries, instead requesting to receive an amount k_n . This request is usually made on a one-period ahead basis, so that the supplier has time to adjust delivery. The swing amount k_n is subject to the constraint $k_{\min} \leq k_n \leq k_{\max}$, where $k_{\min}$ (respectively, $k_{\max}$) is the minimal (respectively, maximal) allowable one-period delivery volume. The timing of these exercises is at the discretion of the buyer. Thus, depending on the needs of the buyer, the amount received can be swung up or down up to N_c times.

Let Y_n denote the discounted present value of the net cash flow beyond the income expected from the baseload contract, due to the exercise of a swing right on date n . Assuming that the cashflow amount is linear in the swing volume and no other constraints are present, it is optimal to always apply full (bang–bang) volumetric exercise, that is, $k_n \in \{k_{\min}, k_{\max}\}$. It follows that

$$Y_n = e^{-rn}(k_n - \bar{K})(P_n - \bar{P}) \quad (1)$$

where P_n is the spot price of the commodity in period n , and r is the discount rate for one period. Note that if the exercise decision was made *before* n , then Y_n in equation (1) may be negative.

Take-or-Pay Provisions

To bound possible swings from the baseload contract, global volume constraints are often imposed. A take-or-pay provision adds the constraint $S_{\min} \leq \sum_{n=1}^N k_n \leq S_{\max}$, where $S_{\min}$ (respectively, $S_{\max}$) is the minimal (respectively, maximal) total volume over the N periods. Thus, the buyer must place his or her total cumulative consumption within a predefined volume band. This rule is enforced *via* penalties on the buyer (hence take or pay) if the provision is violated.

Nomination Contracts

A nomination contract is a variant of a swing option, where the swing amounts are permanent. Thus, changing the nomination amount from $\bar{K}$ to k_n implies that the new baseload amount will be k_n for the remainder of the contract. Such ratcheting rules are common in pipeline contracts.

Refraction Periods

Some contracts impose a minimal refraction period δ between consecutive swings to prevent too rapid an exercise. Refraction periods also appear in research papers that consider swing options in continuous time; see the section Valuation and Theoretical Issues below.

Most existing contracts combine several of the above features and also include further custom rules, so that “vanilla” swing options are actually a rarity. Before proceeding with our discussion, we give a few examples of real-life swing contracts.

Swing Option in the Natural Gas Market

Consider an industrial natural gas consumer that wishes to hedge its future input costs. The consumer does not know consumption volume precisely (which depends on demand for output, operational

constraints, other suppliers, etc.), but has some volume range based on past usage. The consumer purchases a month-long swing option to offset this “volumetric risk” exposure. The swing option gives the consumer the right to buy up to 10 000 MMBtu at the price of $\bar{P} = \$6$ in each of the four weeks; the total volume must be between $S_{\min} = 10\,000$ and $S_{\max} = 30\,000$ MMBtu over the month. In this example, $N_c = N = 4$, $k_{\min} = \bar{K} = 0$, and $k_{\max} = 10\,000$.

Recall Option for an Oil Pipeline

An oil pipeline company delivers oil from hub A to an industrial customer at point B. The pipeline plans on delivering 1000 bbl/day for the next month at the forward price of $\bar{P} = \$100/\text{bbl}$. However, owing to pipeline congestion, supply disruption, or engineering problems, the pipeline may be unable to fulfill its obligation. To mitigate this risk, the pipeline purchases a recall option from its customer. Upon giving notice the day before, the recall option gives the pipeline the right to withhold delivery (or deliver less than the baseload amount) on up to three days during the month. In this example, $N_c = 3$, $N = 30$, $k_{\min} = 0$, $\bar{K} = k_{\max} = 1000$. Similar interruptible delivery contracts are common in electricity markets; see [10, 16, 22].

Load Serving Contract for an Electricity Utility

Electricity swing options have become popular with the deregulation of electricity markets, which led to volume risk management by the power serving entities (PSE). A PSE is obliged by law to provide power to its customers and must adjust its production to maintain equilibrium with the fluctuating demand. Such dynamic load management can be synthetically reproduced by a swing contract that the PSE in effect sells to its customers. By buying an offsetting swing option on its input fossil fuel (such as natural gas), the PSE can transfer the corresponding volume risk exposure to other market participants.

Valuation and Theoretical Issues

From a financial engineering perspective, a swing option is an exotic compound timing option on the underlying commodity asset. More precisely,

it closely resembles a series of American options. Indeed, if the number of swing rights is $N_c = 1$, then the swing collapses to the usual American option (see **American Options**); if the number of swing rights is equal to the number of periods ($N_c = N$), then the value of the swing contract is equal to a strip of European options for each period. Let us denote by $V(t, m, p)$ the value of owning a swing contract on date t with m remaining swing exercise rights and current price p of the commodity. Then the following *a priori* bound is always true irrespective of the underlying price process:

$$m \cdot EC(t, p) \leq V(t, m, p) \leq m \cdot AC(t, p) \quad (2)$$

where EC (respectively, AC) denotes the value of a European (respectively, American) option with expiration date N .

In the following discussion, we assume that $k_n \in \{0, 1\}$; modulo constant scaling this is equivalent to full volumetric exercise. To set up a mathematical model, it is necessary to construct a framework for the multiple exercise opportunities. Recalling the concept of stopping times, define the set of m -tuples of stopping times used to model the multiple exercises as

$$\begin{aligned} \mathcal{S}_{\alpha, \beta}^{(m)} &= \{\bar{\tau} = (\tau_1, \dots, \tau_m): \tau_i \text{ stopping time} \\ &\text{and } \alpha \leq \tau_1 < \tau_2 < \dots < \tau_m \leq \beta\} \end{aligned} \quad (3)$$

Then the optimal multiple-stopping problem corresponding to a basic swing option with maturity T reduces to computing

$$\begin{aligned} V(t, m, p) &= \sup_{\bar{\tau} \in \mathcal{S}_{t, T}^{(m)}} \mathbb{E}_t[Y_{\bar{\tau}}], \quad \text{where } Y_{\bar{\tau}} := \sum_{i=1}^m Y_{\tau_i} \\ \text{and } P_t &= p \end{aligned} \quad (4)$$

Beyond finding the value of the supremum in equation (4), it is of interest to know whether this supremum is actually attained (existence of optimal swing exercise strategy), and if yes, finding a computational algorithm giving a “minimal” set of optimal exercise times $\bar{\tau}$. For models of equation (4) in continuous time, the refraction time constraint $\tau_i \geq \tau_{i-1} + \delta$, $\delta > 0$ must be added to equation (3); otherwise $\tau_{i-1} < \tau_i$ is vacuous.

The problem (4) is best solved by an inductive procedure based on the solution of a sequence of

single-exercise American options. For example, Carmona and Touzi [9] have proved that

$$V(t, m, p) = \sup_{t \leq \tau \leq T} \mathbb{E}_t [Y_\tau + V(\tau, m - 1, P_\tau)] \quad (5)$$

where the maximization is over all stopping times τ , and where $\mathbb{E}_t$ denotes conditional expectation at time t . Equation (5) is of the same flavor as the American/Bermudan option problem, but with additional state variable m .

In a Markovian setting, an optimal swing exercise policy is characterized by an *exercise boundary* B , similar to American options, that is, the exercise boundary divides the commodity price space into a *continuation region*, where the holder of the swing does nothing, and an *exercise region*, where it is optimal to exercise a swing right. However, analysis of the swing exercise boundary is complicated by the fact that today's exercise reduces future delivery flexibility. Thus, the swing exercise boundary is a function both of time and number of remaining rights, $B = B(t, m)$. In certain settings [6, 9], it can be shown that $B(t, m)$ is connected, and, moreover, is monotone in number of rights m and, similarly, is monotone in t . However, general properties of $B(t, m)$ remain unresolved. An excellent summary of the structural features of swing options can be found in the book by Eydeland and Wolyniec [15, Chapter 8].

The major difficulties in valuing and analyzing swing options arise because of the high-dimensional setting and the contract's path-dependent features. Analysis of a basic swing option involves two state variables, namely, the current price P_n and the remaining number of exercise rights M_n . If a take-or-pay provision is present, then one must also consider the current cumulative volume $S_n := \sum_{j=1}^n k_j$. Both the M and S state variables depend on the particular swing exercise policy and are therefore path and control dependent. This precludes simple application of dynamic programming to equation (5). Moreover, models of underlying commodity price processes (see **Commodity Price Models**) are often complex and include multiple factors to capture the observed seasonality, mean reversion, and nonlinearity in prices. Recall that if the exercise decision is made on a forward basis, modeling of the spot-forward relationship (see **Commodity Forward Curve Modeling**) is also needed.

To illustrate the difficulties involved, consider a simple binomial tree model that assumes a one-dimensional random walk description of the underlying commodity price (P_n). To price a swing option, we then need to set up a *forest* of N_c such trees, with a tree for each possible number of remaining exercise rights. One can then proceed using the backward dynamic programming algorithm like for standard American options (see **American Options**), where a swing exercise triggers a jump from a tree with $M_n = m$ remaining rights to a tree with $M_n = m - 1$. Such an algorithm imposes memory and space constraints and raises efficiency issues. More sophisticated models might involve multiple factors or jumps (or take-or-pay provisions) and would require even more complex forests of trees.

Historical Perspective

Initial discussion of swing options appeared in the early 1990s in energy practitioner magazines; see, for example, [3, 11, 12]. At the same time, a limited literature studied the embedded multiple exercise opportunities [14, 25, 30]. Theoretical treatment of swing options was first carried out rigorously by Jaillet *et al.* [21]. The connection to multiple-stopping problems was established by Carmona and Touzi [9], who showed in a certain mathematical framework that a swing option is equivalent to N_c compound American (optimal stopping) options on the underlying; see also (5). This fact suggests pricing of swing options based on existing methods for American options. In a simplified model, with single underlying risky asset, swing options could be, for example, priced by solving partial differential equations like in the classical Black–Scholes theory (see **Finite Difference Methods for Early Exercise Options**). However, nonlinearities rule out solutions in the classical sense, and complex free boundaries make the design and control of numerical schemes quite a challenge.

To overcome these challenges, a variety of approaches have been suggested, including other partial differential equation methods ([13, 31] and see **Finite Element Methods**), stochastic dynamic programming [2, 17], the aforementioned binomial and trinomial trees ([21] and see **Tree Methods**), Monte Carlo simulation methods ([4, 16, 20, 27] and see

Bermudan Options), approximate techniques ([14, 23, 29] and *see Exercise Boundary Optimization Methods*), and optimal quantization (*see Quantization Methods* and [1]). Also see [16, 19, 24, 32] for analytic pricing of swing contracts under certain exotic models for the underlying commodity and [28] for game-theoretic aspects of swing options. Beyond the basic contracts, the modern practitioner/research trend is to value swing options using simulation tools that can achieve excellent computational complexity properties with respect to underlying models. However, as a trade-off, the error analysis of many simulation schemes is difficult, and usually only a lower bound on price can be obtained.

Hedging Issues

Hedging of swing options can be carried out in the same framework as American options. However, several additional issues make hedging difficult in practice. First, recall that many buyers of swing options are industrial customers. Empirical evidence [15] suggests that such buyers often exercise suboptimally to meet their other obligations (e.g., as suppliers of electricity). Suboptimal exercise may be justified if the spot market is not sufficiently liquid, as is the case in many commodities, especially those with strong locational characteristics. This leads to nontrivial financial implications to sellers of swing options who hedge optimally.

Secondly, swing exercise decisions are typically made one-day-ahead on the basis of forward prices. Since the cashflow is based on spot prices, basis risk between forward and spot price becomes a cause of concern (both to buyer and seller of swing contracts). This is particularly so in electricity markets, where the commodity is nonstorable and there is no definite convergence between day-ahead and real-time prices.

The underlying commodity market may be financially incomplete (*see Complete Markets*) for other reasons. As such, the seller of the swing option cannot fully hedge his or her exposure and therefore the no-arbitrage risk-neutral valuation method might not make sense. Finally, in some less liquid markets, the buyer may be exercising market power by manipulating demand through his or her swing policy and therefore affecting future prices.

Extensions and other Contracts with Multiple Exercise

With wide use of swing options, other modifications to the basic contract have become common.

Chooser Flexible Caps

A cap contract with strike $\bar{P}$ on a three-month interest rate is a portfolio of options on the quarterly interest payments that have to be made. Let us assume that the life of the contracts is N quarters, and the nominal is X . Each individual option is called a *caplet*. It covers one of the N quarters, and its payoff is $X \cdot \Delta t \cdot (L_3 - \bar{P})^+$, where Δt is the day-count fraction, and L_3 denotes the quarter-end three-month LIBOR rate. A *chooser flexible cap* is a contract such that, at each reset date, the holder of the contract has the right to decide whether to exercise that particular caplet and count it as part of the N_c allowable ones, or spare it for later use, each decision being final. The remaining caplet rights expire worthless if not used before the end of the N periods. A chooser cap reduces to a regular cap (*see Caps and Floors*) when $N_c = N$, while it can be viewed as a standard American/Bermudan option on the interest rate L_3 when $N_c = 1$. Valuation of such contracts has been studied in [27].

Two-sided Swing Options

Some physical contracts combine the swing and recall features described above. Thus, the baseload contract is augmented with N_r recall rights for the party delivering the commodity, and N_c swing rights for the buyer. The interaction of these rights leads to a stochastic *game* between the two counterparties, with the buyer being the minimizing agent, and the seller the maximizing agent. Valuation of such two-sided swing options is related to Dynkin games as explained in [5].

Gas Storage

The owner of a gas storage facility attempts to maximize revenue by injecting gas into storage when prices are low and withdrawing gas when prices are high. Exercise of such flexibility can be

viewed as a nomination swing option where k_n is allowed to be both positive and negative (to model withdrawals). The volume constraints $S_{\min} \leq S_n \leq S_{\max}$ then correspond to the physical size constraints of the facility. Gas storage valuation is complicated by additional storage costs, which add further path dependency to the problem; (see [4, 8]).

Tolling Agreements

In a *tolling agreement*, the buyer is granted use of a commodity-generating facility for a fixed period of time. The buyer can then run the facility when commodity price is high and keep it shut down when prices are low. This is again a nomination swing option with additional engineering constraints, such as fixed switching costs. Modeling of such contracts fits within the more general framework of optimal switching problems [7, 18].

Employee Stock Options

Company employees are often granted multiple stock options in their employers (see **Employee Stock Options**). Partial exercise of such options by risk-averse employees is similar to a swing call option, as multiple exercises must be considered [26].

Emissions Trading

There are numerous forms of environmental impact associated with human activity. The best known in the energy sector are emissions to air, particularly carbon dioxide, sulfur dioxide (SO_x), nitrogen oxides (NO_x), and other emissions such as mercury. Regulatory intervention can limit these emissions in a number of ways.

Our aim here is to show how management under the “cap-and-trade” regulatory mechanism for emission limitation can be partially modeled in terms of standard instruments for financial derivatives. We discuss briefly how similar modeling techniques can be applied to more complex environmental factors such as emission of particulates, impact on water, and impact on local amenity. The modeled entity is principally the price of the cap-and-trade allowance, and we also briefly consider the shadow price of other forms of environmental limits, and other features, such as the emissions cap and its allocation.

The politics, economics, and science of emissions impact and emission abatement, and the various regulatory schemes, are well covered in other texts and are not covered here. We offer a caveat here; while we characterize the microeconomics of emission abatement using supply and demand curves, we should be aware that the long-term nature of emission impacts are, in some aspects, more amenable to a classical economic analysis than the neoclassical analysis that standard quantitative approaches to derivative instruments necessarily entail.^a Beyond the politics and economics, the essential challenge in the modeling of allowance prices in particular, is the capture of the essential features of the allowance, so that the pricing problem can be framed in terms of standard quantitative analysis of derivatives.

Regulatory Interventions

The key methods for regulatory intervention can be divided into (i) technology prescription; (ii) instantaneous limits which are usually measured by instrumentation; (iii) annual limits which are commonly measured by estimation using the average composition of the fuel; and (iv) taxes and subsidies. Commonly, more than one intervention will apply.

An efficient form of regulatory intervention to optimize emission abatement is a tax at the marginal damage rate, if known accurately. See [6] this may be regional, periodic or otherwise varying across time, and stochastic according to the evolution of information. This is currently impractical for a variety of reasons including agreement on current benchmarks, definitions, and included sectors, changing purchasing power of international currency in different countries, and the difficulty in securing agreements.

In the pure cap system, each registered source (or collection of sources under one company) of emission has an annual limit that may not be exceeded and which is allocated, with or without cost, to emitters. Relative to the pure tax system, this system has the practical benefit of easier implementation, limited step change, and relatively straightforward definition of source, which can change over time. So, for example, international air travel can be included in the scheme after its inception. The total cap should, in theory, be increased as the emission comes within the scope of the scheme.

In the cap-and-trade system, each source is assigned an emission allowance for the compliance period.^b The source can emit more if it purchases allowances from other sources, and can sell allowances if it can reduce its emissions below the cap. Initial allowances are commonly related to past emissions, and allocations are reduced over time. Ultimately, the free allocation of allowances can be reduced to zero, with the central administrator selling a fixed (i.e., maintaining a set amount of emissions) or variable (maintaining a set tax rate) amount of allowances.

Here, we pay attention to the quantitative analysis of allowance prices in the cap-and-trade system.

Framework

From an analytic perspective, the most important features of the regulatory framework are as follows:

- The compliance periods—length and phase.
- Banking and borrowing—regulatory exchange rate between allowances in different compliance periods.^c
- The use of “grandfathering” for allocation—the extent to which caps are dependent on historic emission.

- Allocation to new facilities and withdrawal for closing facilities.
- Buyout mechanisms—a penalty mechanism within the overall scheme, or government withholding of their allowance allocations, allowing a penalty mechanism within the country without affecting the global cap.
- Fines—for emitting without allowance.
- Relationship between schemes—allowed exchange between schemes, double count of emissions, and emissions missing from schemes.
- Recycling of fines, buyout, and other revenues to allowance “producers”.
- Sequestration allowances for sinks.
- Coverage—countries, sectors, producers, and consumers.
- Restrictions and other scheme details—for example, in the United Kingdom, Climate Change Levy Exempt Certificates can be borrowed for only five periods in a row.

Using Supply Stacks

Let us first assume that the only way to reduce the emission is to “switch on” a series of installed abatement technologies at the expense of a (upward sloping and curving) marginal cost. Assuming steady demand and a constant generation mix, the abatement “stack” can be simply represented. The effect of a rate limit in tonnes per day on the “production stack” of allowances is linearly related to the residual time in the compliance period (see Figure 1).

In the absence of banking and borrowing of allowances (which we treat as a 0% and $\infty\%$ inter-compliance period exchange rate, respectively), then it is easy to see not only why allowance prices become

extremely volatile as the end of the compliance period arrives but also how this volatility is itself volatile according to the prevailing use of technology (i.e., whether we are operating at the higher or lower cost part of the allowance production curve).

When considering the installation of new technology to produce allowances, we can treat each technology as having a capital and fixed cost (the option premium) and a marginal cost (the strike price for the technology owner). We expect our technology to endure across compliance periods and hence this creates a shadow exchange rate and option inter-dependence between periods. If we apply a simple rule that ensures an exact recovery of total fixed and variable costs in each compliance period, then the marginal price offered is stochastic according to the past and planned fixed cost recovery within the compliance period. So, for example, the offer cost from a technology may be lower if it has run at a high load factor during the compliance period and thereby recouped most of its fixed costs, or as a result of high forward prices within the compliance period the planned load factor is high and therefore the offer cost can be relatively low.

Allowances can be “produced” in a number of other ways including demand reduction, sequestration and offset, and banking and borrowing.

Sources of Uncertainties

There are three principal sources of uncertainty:

- production cost stack
- demand for energy—high energy demand creates high allowance demand
- regulatory change.

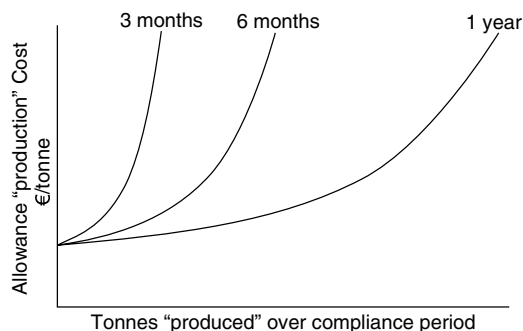

Figure 1 The cost curve for allowances in relation to the horizon to the end of the compliance period

Regulatory change uncertainties are (i) change in framework; (ii) change in coverage; and (iii) changes in the figures under the framework (cap, buyout price, banking and borrowing rates, etc.). These changes are themselves influenced by changing knowledge about damage rates, sector outputs, and political effects.

Price Characterization

If there is no banking or borrowing across a compliance period, then the steepening of the abatement stack that can be applied to the residual period causes an increase in volatility. Since the compliance period is set in calendar time, rather than having a rolling horizon, the volatility term structure is therefore not stationary. Similarly for any nearby compliance period, there is no equilibrium price to revert to, although there are a number of reference prices, such as the short-run marginal cost of abatement, the fully loaded cost of abatement (loading the fixed costs onto the short-run marginal costs to ensure precise cost recovery over the compliance period), value of lost load, buyout prices, and gaming prices. An example of a gaming price is the price outcome from Cournot competition between allowance producers.

In the same way that monthly futures can be regarded as derivatives of forward price curves with daily resolution, compliance period allowances can be regarded as derivatives of the daily allowance price curve, which itself is constructed from the abatement stack. In common with futures, allowances can be regarded as “cheapest to deliver”. There is never merit in submitting the allowance prior to the end of the compliance period, but due to the limit on the “production rate” of allowances, the rate of physical production of allowances can have complex structures within the compliance period. This is a standard optimization problem used, for example, in hydro reservoir optimization. The cost of capital should be taken into account when optimizing. The forward price curve for allowances in each compliance period is a discrete vector, with as many forward allowance prices as there are actual and expected compliance periods. To a degree, this allows us to treat the long-term problem as a “Bermudan” rather than “American” one, although the latent price structure within the compliance period is important.

- Long-term prices—since the economic theory is that the regulatory cap should be adjusted such that the cost of marginal abatement enacted is equal to the marginal damage rate, there is, in theory, a long-term equilibrium price. Indeed, since climate change has such universal impact, we may regard the optimal long-term allowance price as a , and possibly *the*, international numeraire asset.^d However, the uncertainties surrounding the marginal damage rate, the difficulty of denominating the allowance in currency, and the difference between practically achievable allowance prices and the “ideal” price are such that the long-term price has a very high degree of uncertainty associated with it, and the long-term price can change on an instantaneous basis.^e Hence we should regard the long-term price as highly volatile.
- Negative prices—market prices for allowances cannot have negative values, and hence allowances can be regarded as assets in this sense. However, under a pure cap regime, the shadow prices for allowances can be negative since ongoing allocations are related to past emissions, and production below the allocation risks an allowance reduction in future.
- Embedded options—schemes such as the Renewables Obligation scheme in the United Kingdom can have buyout prices, which allows the retail supplier to pay the buyout price instead of procuring allowances. So the cost is capped for retail suppliers, while the Renewable Obligation Certificate (ROC) price, created by the recycling of buyout revenues, is higher and volatile. However, if the cost of ROC production falls below the buyout price, suppliers will buy ROCs instead of paying the buyout. Therefore retail suppliers have embedded put options in their compliance costs. The compliance cost therefore has a stochastic element even if the buyout price is known.
- Government influence—there are a number of mechanisms that can be used by the government to adjust prices. For example, the government can allocate to sectors less than the national limit, leaving it with “hot air”. This increases the cost of compliance. The government can then release the hot air at low or high prices to sectors of its choice. The impact on price depends on the effect that discretionary allocation has on physical production of allowances. Given that the market

solution in theory delivers the neoclassical optimum, then from a modeling perspective, government influence in allocation should be regarded as increasing allowance prices.

- Path dependence—the two key drivers to path dependence are the cost structures of emission abatement, and the effect of the fixed cap on emissions under conditions of stochastic energy consumption. We have already seen that if “allowance producers” recover their full costs in each compliance period, that their offer price above marginal costs depends on the fixed cost recovery to date. So, for them, high historic compliance prices have a depressing effect on forward allowance prices within the compliance period. The fixed volume of the cap has the opposite effect. If energy demand has been high in the early part of the compliance period, then emissions will have been high, and the residual cap volume will have been depleted, which has an elevating effect on allowance prices. The modeling of this is very similar to that for an energy complex, which has an element of fixed energy amount. An example might be a complex with hydro reservoirs and combined cycle gas turbines. We return to the swing modeling in an electricity context below.
- Cost of risk—the cost of risk^f for traded commodities is the cost of risk of the marginal player. As the compliance period draws to a close, each player ensures that they are not short and places decreasing reliance on the market to close short positions. This may manifest itself as a substantial negative cost of risk (i.e., forward price above expectation price for the last submission date of the compliance period) in the medium short term, with a possibly positive cost of risk in the very short term as emission uncertainty decreases and installations hold (and can sell) long allowance positions. There are pressures for long-term risk to be in either direction. Allowance producers (who have positive cost of long-term allowance price risk) are commonly the same entities as the emitters (who have positive costs of long-term energy price risk).
- Hidden variables—the cost of abatement is highly dependent on the power generation technology mix operating. So, for example, low gas prices will cause combined cycle gas turbines to displace coal-fired power stations,

and the abatement stack will be dominated by technologies at coal plant. The allowance price depends on the price paths of the major fossil fuels (coal, oil, gas). A critical hidden variable is the amount of cap remaining in the compliance period.

Instrument Pricing

Here we consider that the underlying commodity is the emissions allowance for some examples of exchanges, see Nordpool, European Climate Exchange and EEX, or its index price.

- Modeling—we have the usual mixture of static optimization, stochastic dynamic programming using multidimensional trees/forests, and semianalytic techniques available. Owing to the high degree of importance of hidden nonstationary variables^g in influencing the forward allowance price, the application of one-factor Monte Carlo techniques should be undertaken with some caution.
- Options—emissions options are traded, with the main instrument being the European option. They are important because of the effect that allowance prices have on the operation of energy installations. This is best illustrated by using the cap-no-trade system with a single power plant as an example. Consider a simplified power station that is operationally flexible, never fails, has no variability in its emission abatement, and has a pure cap-no-trade regime. It can be regarded equivalently as a family of European fuel-plus-allowance-to-power options with the internal market allowance price (i.e., the shadow price) adjusting such that the compliance period limit is exactly reached, or a family of European fuel-to-power options with the number of exercises limited by the cap (variously called *swing*, *flexi-cap*, or *take or pay*). We note in each case that the option value is path dependent. If the key factor prices for electricity (coal, oil, gas, etc.) and the price of electricity are all regarded as exogenous to allowance prices, then the allowance price can be modeled using standard techniques for hydro reservoirs (the cap being treated as a reservoir, with limitations on physical production rate). In reality, these factors have interdependency that is high, periodic, complex, and variable. Across the

entire global energy complex, the emission limit, net of sequestration, is reached, but the modeling of this is excessively complex.

At any instant, optimization methods provide the efficient marginal and total cost of abatement to meet the cap. Dynamic marginal prices arise from exogenous shocks to the system, such as shock or to the cap limit. This visualization is particularly useful in assessing the codependence between the key factors and, in fact, the only truly exogenous factor in the early stages of the scheme is the cap itself. In the later stage, if the scheme is efficient, the exogenous factor is actually the allowance price.

- Intercompliance period swaps—the swap rate is determined by the caps, the abatement demand (caused by energy consumption), the abatement cost stacks in the two compliance periods, and the rules such as those on banking and borrowing and on interscheme fungibility such as the clean development mechanism for greenhouse gases.
- Compliance period swaptions—in the absence of banking and borrowing within the scheme, the swaption volatility is a result of (i) shared economics between the periods and (ii) activities that can “produce” allowances in one period at the expense of the other. In economics terminology, these are complements and substitutes, respectively. An example of the former is as follows: if a high allowance price in the near-compliance period makes an abatement scheme attractive, then while the factors that made the near-period allowance price high might have a similar effect on the later period, the enactment of the abatement scheme might have a depressing effect on the allowance prices in the later period. An example of the latter is the use of physical and commercial storage in the energy complex. For example, if a full hydro reservoir is emptied in the first compliance period, then the carbon intensity of production will be low in this period and high in the next. The ability to adjust the release of water therefore has the economic result of storage of allowances, equivalent to banking and borrowing.

Intercommodity Price and Price Movement Relationships

First consider a simple system in which we have one coal- and one gas-fired power stations in country, an in-country, cap-no-trade SO_x regime for the coal-fired stations, exogenously determined nonseasonal coal and gas prices, exogenously determined inelastic domestic demand for power, and an international cap-and-trade CO₂ scheme. Let us simplify the problem by ignoring fixed costs and assuming that the power stations offer power at the variable cost of fuel and allowances. Finally let us begin by assuming that coal is cheaper than gas on an efficiency adjusted basis.

The number of hours that the power price is set by the coal price is set by the minimum of (i) the number of hours for which the coal-fired capacity is sufficient to satisfy demand; (ii) the number of hours that the coal-fired generation can run under the SO_x cap; and (iii) the number of hours for which the coal price is less than the gas price.

Figure 2(a) shows this. First for a nonseasonal gas price, we can see that for the hours on the right, the CO₂ price affects the power price by the effect on coal-fired costs (roughly speaking 0.9 t CO₂/MWh), and for the hours on the left the CO₂ price affects the power price by the effect on gas-fired costs (roughly speaking 0.4 t CO₂/MWh). In the middle, the power price is raised as a result of the result on coal-fired hours, but this is mitigated by the lower carbon costs for gas-fired generation.

Figure 2(b) shows the impact of seasonality in gas prices. This can either increase or decrease the amount of gas-fired generation.

Here, we have taken the CO₂ price as exogenously determined and examined the effect of power prices. If we instead wish to view the effect of demand variation, demand elasticity, gas prices, coal prices, SO_x prices (or shadow prices), then we allow these to change and examine the effect on the volume of CO₂ allowances consumed, and thence construct the stack of amount of CO₂ allowances consumed in relation to CO₂ prices to find the price elasticity of CO₂ allowance demand.

Correlation and Cointegration

Correlation term structures—we have noted a number of features that reduce the tractability of correlation analysis. These are as follows:

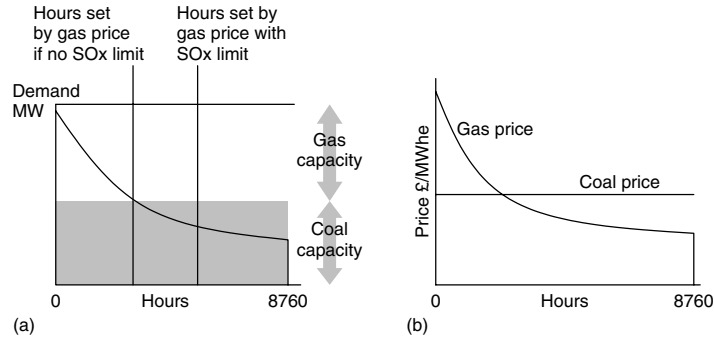

Figure 2 (a) Impact of restriction on coal-fired hours on price setting plant. (b) Effect of gas price seasonality on the number of hours for which gas price is cheaper than coal

1. Path dependence.
2. The “fundamental” long-term “value” of CO₂ allowances, associated with the uncertainty of this value and the difficulty of driving allowance prices to this value through adjustment of caps.
3. Complex co-integration relationships in the energy complex.
4. Nonstationarity of allowance price term structures.
5. Complex periodicity (daily, weekly, annual) in relation to the compliance periods.

While there are price or price return correlation measures that can be constructed, such as between commodities in the current or next compliance period, or between compliance periods, the nonstationarity and periodicity issues are such that it is very difficult

at this stage to apply this in a useful way for derivative pricing.

Other Kinds of Limits

When running a power station fleet or other physical complex, with multiple commodity inputs and environmental and amenity impact outputs, it is helpful to construct shadow prices to optimize the profitability of the operation. The theoretical approach is to use Lagrange multipliers, and the equivalent effect can be modeled by optimizing the operation subject to constraints, which may vary. For example, the combustion of a coal that is low in sulfur, and therefore SO_x, may entail high NO_x, particulates, carbon in ash, and ash. Figure 3 shows this in generic form, where the limit for factor X could be of various forms,

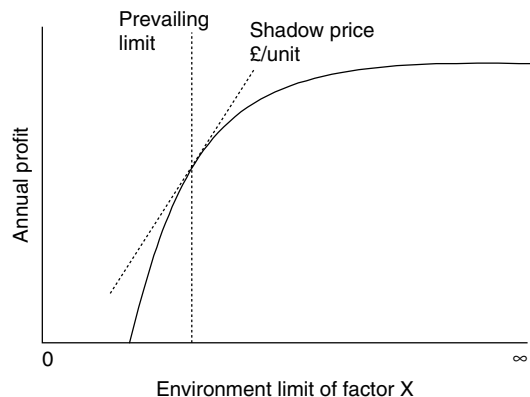

Figure 3 The shadow cost of complex environmental limits

such as height or temperature of water body, road traffic for bulk transport, or local air quality.

Conclusions

1. For small complexes we can limit the number of exogenous variables. For example in a country with a SOx cap-and-trade, we initially model all technologies and costs as fixed. We then model the SOx price change from a shock to the cap, or fuel prices, or both.
2. For a large complex such as the European Emission Trading Scheme under the Kyoto protocol, the same methods apply in principle, but the exogenous variables are more complex. In the early stages of the scheme, the cap is the exogenous variable. In the later stage it is the monetized marginal damage rate.

End Notes

^aThere are two particularly important considerations here. First that the ambient trading price of allowances that results from the cap is not exogenously determined but is closely related to the societal damage cost of emissions, and secondly that the interest rate used for the damage cost is driven not by the rolled-up money market account in the Arrow–Debreu market economy but the intergenerational interest rate in the overlapping generations economy.

^bFor an early description of the sulfur dioxide scheme in the USA, see [3].

^cThis is socially efficient and refer to [5].

^dAs mentioned in the beginning, we should be aware that the concept of a numeraire asset is less easily applied in classical economic analysis.

^eFor fitting of jump modeling to EEX data, see [2].

^fThis can be expressed in terms of convenience yield—see [1].

^gFor empirical fits using GARCH modelling, see [4].

CHRIS HARRIS

Weather Derivatives

Weather is not only an environmental issue but also a key economic factor, as recognized by the former US Commerce Secretary, William Daley, in 1998, when he stated that at least USD 1 trillion of the world economy is weather sensitive. The risk exposure is not homogeneous across the globe and some countries, usually those heavily dependent on agriculture, are more sensitive than others. It also includes a large range of phenomena such as modifications in temperature, wind, rainfall, and snowfall.

Weather risk has some specificities compared to other sources of economic risk: in particular, it is a local geographical risk that cannot be controlled. The impact of weather is also very predictable: the same causes will always lead to the same effects. Moreover, weather risk is often referred to as a *volumetric risk*, its potential impacts being mainly on the volume and not (at least directly) on the price. This explains why hedging of weather risk *via* the trading of commodities futures is difficult and imperfect. For example, oil futures price does not depend solely on demand (cold winter) and can be high even if the demand is low as in the case of a war, for instance. Volumetric risk is imprecisely compensated by the price variation in the futures position.

Usually, it is possible to hedge against risk by contracting some insurance policies. However, this is not really a possibility for weather risk for two main reasons: first, it is more a high-frequency, low-severity risk and, second, the same weather event can generate economic losses for some agents and some gains for others. To deal with this risk, some financial contracts depending on weather conditions (temperature, rainfall, snowfall, etc.) were created and introduced on the financial market 10 years ago. They are called *weather derivatives*.

Weather Derivatives

Weather derivatives are financial instruments whose value and/or cash flows depend on the occurrence of some meteorological events that are easily measurable, can be independently authenticated, and are sufficiently transparent to act as triggering underlyings for financial contracts. Typically, location is

clearly identified and measurement is provided by independent and reliable sources. The underlying meteorological events can be considered as noncatastrophic.

According to the Weather Risk Management Association (WRMA), the financial market related to weather has two main facets: the management of the financial consequences of adverse weather for those with natural exposure to weather, and the commercial trading of weather risk, both in its own right and in conjunction with a variety of commodities.

The first weather transactions took place in 1997 between Enron and Koch Industries. These transactions were the result of a long thinking process by Koch, Willis, and Enron aimed at finding a means of transferring the risk of adverse weather. These deals followed the deregulation of the energy market in the United States (transition from an oligopolistic position to a status of mere participant in a competitive market) and were based upon some temperature indices to compensate the energy producer in case of a mild winter.

The most common underlying is related to the notion of degree day, which is expressed as the difference between a reference level temperature (65°F or 18°C) and the average daily temperature T . The average is computed between the maximum and minimum recorded temperature over a particular day. A heating degree day (HDD) is defined as follows: $\text{HDD} = (65^{\circ}\text{F} - T)^+$, where $(.)^+ = \max(., 0)$. The bigger the HDD is, the lower the temperature is, and as a consequence the larger the demand for heating will be. Similarly, a cooling degree day (CDD) is defined as follows: $\text{CDD} = (T - 65^{\circ}\text{F})^+$.

The definition of a temperature index in those terms reflects the close relationship between the energy sector and the weather derivative market. Daily results are often cumulated to give a total on a given period, such as a week (Xmas–New Year's Eve, a sport event), a month (sales period, harvest period), or a quarter (summer holidays, opening season of a resort).

The Weather Derivatives Market

Most of the transactions are tailor-made and part of the OTC (over the counter) market. Usually, OTC transactions are realized within the ISDA standards (master agreement standards of the International Swap and Derivatives Association), which

provide standardized contracts aimed at easing OTC transaction processes. Some transactions go through specialized brokers but most of them are done without any intermediaries. It is not surprising that these tailor-made structures better suit the management of weather risk and the needs of the various players on this market. The organized markets are however rather successful, mainly because of the transparency, liquidity, and security they offer. Among them, the most predominant one is the Chicago Mercantile Exchange (CME), which offers several types of contracts.

Some attempts were made in Europe to launch an independent organized market for weather derivatives. In November 2005, Powernext, which is a European energy exchange based in France, and Meteo-France launched the quotation of national temperature indices for nine European countries and different types of indices. This initiative was further developed with the launch in June 2007 of Metnext, a joint venture between Meteo-France and Euronext, specialized in indices for weather risk management.

Besides organized markets, since the beginning of the weather market in the late 1990s, electronic trading platforms have always played an important role in the development of the market, especially Enron's platform, in the early days. Many big market players have such a platform, and, in particular, Spectron is rather important in Europe.

Microinsurance and Weather Derivatives

One of the most spectacular developments of weather derivatives lies, however, in the specificities of this widespread risk, with among the most exposed ones being those that rely on agriculture. Microinsurance, that is, a microfinance service that allows poor individuals to insure possessions, such as livestock or crops, has already seen the fantastic potentiality offered by weather derivatives. Therefore, it seems natural to see the World Bank as one of the players in this market. Among the various structures of the World Bank, the International Force on Commodity Risk Management (CRM, [4]) has, as its main objective, to deal with the agricultural risk in developing countries, where agricultural risk is defined as "negative outcomes stemming from imperfectly predictable biological, climatic and price variables". The economic and social consequences of this risk being

so huge in some countries, it seems logical to seek some form of protection against this risk. However, even if insurance companies were to write insurance policies against this risk, they would be typically too expensive for small farmers, and the compensation would take too long to be effective, partly because of the claim-checking procedure. The CRM has developed several projects throughout the globe in order to deal with agricultural risk transfer using weather derivatives. Among these projects, the pilot program conducted in India between 2003 and 2006 has been particularly successful. Microinsurance is a growing sector and more projects have been implemented across the globe to protect small- and medium-size farmers from weather risk. Some reinsurance companies have been particularly active in these programs by helping local institutions to implement the insurance schemes.

Pricing of Weather Derivatives

Given the uncertainty and the flexibility in their accounting classification, and also their relative illiquidity, several pricing methods have been suggested for weather derivatives. They can be classified into three main categories: actuarial, financial, and economic. In the following, we briefly present these various approaches, focusing on the (forward) pricing rule of a weather derivative with a payoff H at a future time. Considering forward price allows us to simplify the problem in terms of interest rates and focus on the pricing rule itself.

The actuarial method (*see Actuarial Premium Principles*) uses the fair value corrected by some margin as pricing rule. More precisely, denoting by P the statistical probability measure used as prior probability measure, the (forward) price of the derivative can be obtained as $\pi(H) = E_P[H] + \lambda \sigma_P[H]$. Different authors have studied the impact of the choice of the probability measure on pricing (*see, e.g., [8, 9]*).

The financial methods often assume the weather derivative market to be complete and therefore use the risk-neutral pricing rule $\pi(H) = E_Q[H]$ where the expectation is taken under a unique martingale measure Q . A milder argument consists in assuming the absence of arbitrage opportunities only. In an incomplete market framework, there exist many different methods to price a contingent claim, without

creating any arbitrage opportunity. A rather standard approach involves utility maximization. Any individual wants to maximize the expected utility of his or her terminal wealth in this framework. The maximum price that he or she is ready to pay for the weather derivative is therefore the price such that he or she is indifferent, from his or her utility point of view, between buying it or not. For this reason, the price obtained by utility maximization techniques is called *indifference price* (many references exist on this subject, see, for example, [7] and **Arbitrage Strategy**).

Denoting by u the utility function of the agent we consider, and assuming that there are no interest rates (for the sake of simplicity), the indifference buyer price of H , $\pi^b(H)$ is determined as $E_P[u(W_0 + H - \pi^b(H))] = E_P[u(W_0)]$, where W_0 is the initial wealth (which may be random). The price $\pi^b(H)$, which theoretically depends on the initial wealth and on the utility function, is not (necessarily) the price at which the transaction will take place. This gives an upper bound to the price the agent is ready to pay for the payoff H . The agent will accept to buy the contract at any price below $\pi^b(H)$. In the characterization of the indifference price, there is no question on the volume of the transaction. The potential buyer has two options: either buying one contract or not buying it. There is another possible approach, which consists of determining the price of the contract such that agreeing to buy a small quantity has a neutral effect on the expected utility of the agent. This notion of fair price in that context was first introduced by Davis in [5, 6] and corresponds to the zero marginal rate of substitution price. More precisely, the fair price p is determined such that

$$\frac{\partial E_P[u(W_0 + \theta H - p)]}{\partial \theta} \Big|_{\theta=0} = 0 \quad (1)$$

Finally, the economic approach relies on a transaction price, which is an equilibrium price, either between the seller and the buyer only, or between the different players in the market. Note that a transaction will take place only if the indifference buyer price is higher than the indifference seller's price, which gives a lower bound to the price the seller is ready to accept for the contract. This is a necessary condition for a transaction, and more generally for a market equilibrium, which characterizes the situation where all agents in the market maximize their expected utility at the same time by exchanging their risks (such an equilibrium is also called *Pareto optimal*). Such

an equilibrium approach has been adopted by different authors, for example, [3, 8]. While the first authors look at how weather forecasts can influence the demand for weather derivatives, and hence their price, the latter consider the problem of pricing in an incomplete market, with a finite number of agents willing to exchange their weather risk exposure. The price of the contract is obtained as that of the Pareto-optimal equilibrium.

Design Issues

As shown by various failed attempts of weather risk securitization, in particular the failed issue of a weather bond by Enron in 1999 (see [1, 2] for a detailed study), the design of the new securities appears as an extremely important feature in the transaction. It may be the difference between success and failure. More precisely, as previously mentioned, the high level of illiquidity, deriving partly from the fact that the underlying asset is not traded on financial markets, makes these new products difficult to evaluate and to use. The characterization of their price is very interesting as it questions the logic of these contracts itself. Moreover, the determination of the contract structure is a problem in itself: on one hand, the underlying market related to these risks is extremely illiquid, but, on the other hand, the logic of these products itself is closer to that of an insurance policy. Consequently, the question of the product design, which is unusual in finance, is raised.

Liquidity

An asset is relatively liquid if it can be traded without significant movement in its price. We typically think of an asset for which large quantities can be traded without substantial price movement as being in a deep and liquid market. In effect, a liquid asset can be traded at modest execution cost, even potentially in substantial size. Market events and turmoil in 2007 and 2008 focused attention upon the nature of illiquidity and have led to renewed interest about the meaning of liquidity as the trading activity in many hard-to-value assets declined significantly and the costs of trading such assets rose substantially.

The Kyle Framework

The nature of liquidity is extensively highlighted in the seminal work of Pete Kyle [11], who developed a model of adverse selection and trading cost in a classic analysis of the bid–ask spread with a risk-neutral informed investor and market-makers (*see Kyle Model*).^a In this setting when the investor is informed, he/she possesses a normally distributed signal of the value of the asset, and when uninformed, the investor trades a normally distributed exogenously specified quantity. Under the assumption of a linear equilibrium, Kyle [11] derived the unique solution in which the informed investor's trade is a linear function of his/her signal (optimizing an underlying quadratic decision problem) and the pricing at which a competitive market-maker trades is a linear function of the order flow (under the normality assumptions, this reflects a regression that predicts the expected informational cost conditional upon the order flow as the market-maker cannot distinguish an informed order from an uninformed one). The market-maker's (linear) pricing function is such that the cost of trading a position increases proportionately with its size because of the adverse informational consequences of facing a larger order given the decision rule of the informed agent.

The Kyle framework is consistent with the extent of adverse selection being influenced by current market conditions; in the Kyle context, these conditions are reflected in the structural parameters of the model such as the variability of the signal of the informed and the volatility of the trade of the uninformed. For

example, a spike in adverse selection above normal levels, as illustrated by an increase in the variability of the private signal of the informed, implies that liquidity will decline and the price impact of an order of a specified size will increase.^b

The “No-trade” Theorem and “Lemons”

Another complementary perspective on the nature of illiquidity in an asset market is illustrated by models in which trade need not arise due to informational frictions. For example, the classic “no-trade theorem” in Milgrom and Stokey [13] offers fundamental insights about the nature of illiquidity. The central theorem in [13] is that at a Pareto optimal allocation private signals do not lead to trade. One very simple interpretation that summarizes this conclusion is the “Groucho Marx joke”: Groucho Marx declared that he would not join any club whose standards were low enough such that he would qualify for membership.^c This intuition is closely related to the “lemons” idea that underlies the classic work of Akerlof [1]. In the Akerlof [1] setting, potential buyers of a used car are discouraged from purchasing it in light of the seller's private information. Since the potential seller has more precise information on the quality of the vehicle than the buyer, the seller will only sell those types of vehicles that are less valuable to it than the price that the buyer is willing to pay. The buyer's valuation is not based upon the actual quality of car that he is purchasing, but on the distribution of relatively low types that the seller is willing to allow the potential buyer to purchase. In the absence of a substantial difference in preference parameters and valuation between the potential buyer and seller, the presence of private information will lead to a breakdown in this marketplace and the absence of trading and liquidity. This provides a form of the “no-trade” theorem. Instead, if the preference differences were sufficient, then some trading (or perhaps even a lot of trading) would arise. If the equilibrium were to support a small volume of trading, then only the lowest quality of cars would be traded. In this context, illiquidity is reflected in low volume (quantity) and low quality arising in the marketplace, that is, most investors do not sell their holdings because they regard the market price as inadequate. For example, the ability of the seller to select specific low-value mortgage-backed securities pools for sale (such as in the context of substantial

credit risk those pools not carefully underwritten or which have serious documentation issues) and the extent of adverse selection would have greatly limited the trading of these instruments during portions of the market crisis.

The example that lies at the heart of Akerlof's analysis at least indirectly points to mechanisms by which liquidity can be sustained. If the qualities of the goods being sold were known (transparent) so that there was not private information, then liquidity across the marketplace would be sustainable. Alternatively, if the seller could warrant or guarantee quality to a specified level or alternatively, the buyer could rely upon the seller's market incentives to maintain a reputation for providing an accurate description of quality, then trading would be viable across the quality spectrum. Finally, if the difference in preference valuation between the sellers and buyers were sufficiently great, then these very large potential gains to trade would overcome the adverse selection for at least a significant proportion of the population and lead to trade. Relative to the "no-trade" theorem, trade and liquidity can arise, provided we start at an allocation that is not Pareto optimal.

Trading Volume and Asset Value

An interesting and important dimension of the liquidity of a market is the extent of buying and selling interest. If an asset is relatively idiosyncratic (such as an individual family residence with quirky characteristics), then there is one seller and likely few potential buyers. On the other hand (still within a residential real estate context), some properties may have quite close substitutes (units with similar lay-outs in a high rise condominium or cooperative building) and there could be many potential buyers and sellers. In many market contexts, the level of volume is often viewed as an indicator of liquidity and in the case of futures contracts the extent of open interest would be another such indicator. The connection between volume and prices explicitly arises in several of the key foundational frameworks addressing liquidity issues. For example, in the Kyle [11] framework, a liquid asset is the one in which a modest volume will not move the asset's price very much, so a large volume would be required to move the price substantially. Akerlof's [1] "lemons" analysis associates low trading activity with illiquidity as well as low quality of the goods

being exchanged and low prices. More generally, liquid assets typically have high trading volume and turnover.

Relatively liquid (low trading cost) assets are especially valuable and are the natural assets to utilize in a situation in which the owners anticipate high turnover. For example, liquid assets (such as futures contracts in some contexts) are often used by portfolio managers to adjust or maintain their aggregate exposures (to the direction of the equity market or interest rates), potentially even at relatively high frequencies. Less liquid assets are more appropriate for buy-and-hold exposures. To the extent that an investor owns assets with a range of liquidities, we would expect that the most liquid assets would be sold most often. While lower trading costs would enhance value across the spectrum of potential holding periods, the benefits would be especially pronounced for the potentially most active assets. These effects point to important clientele differences among assets of varying liquidity, which are analogous to clientele effects that differentiate assets that are taxed distinctly. However, just as for all investors (except tax-exempt ones) lightly taxed assets are more valuable than heavily taxed assets, similarly more liquid assets are more valuable than less liquid ones. One interesting theme in empirical asset pricing is that liquidity has emerged as a "priced" factor and that assets with higher trading costs provide higher expected returns without excluding the costs.^d Much of the focus in market microstructure is in assessing liquidity, informational affects, and trading costs.^e

Increasing liquidity enhances the value of assets not just across instruments (i.e., cross sectionally) but also over time (i.e., in time series) on specific assets as market conditions evolve. When liquidity in the marketplace disappears, the value of assets declines. This is illustrated by a range of market crises—including most recently, the subprime mortgage crisis that began in 2007.

Investors as Liquidity Providers

Investors themselves can possess considerable liquidity if they have funds available for investment without incurring substantial costs from selling existing positions. In that sense investors can transfer liquidity among assets and liquidity can move from investor to investor (via the assets) through the trading process.

Some investors even specialize in providing liquidity as illustrated by investors engaged in the traditional market-making function (such as a securities dealer or stock market specialist). Even a retail investor who places a limit order in a limit-order book should be viewed as offering liquidity to the marketplace (investors who hit the book consume liquidity). To a degree the dichotomy between demanders and suppliers of liquidity has been reflected in empirical analyses that focus on the interaction between the order flow and limit-order book.^f

The Self-fulfilling Nature of Liquidity

Liquidity is often viewed as self-fulfilling in the sense that liquidity attracts liquidity.^g For example, even in government bond markets there can be instruments with similar features that attract very different trading interest. The “benchmark” government bond in Japan (and to a degree in the United States) has had a higher price (and lower prospective return), but considerably greater trading interest, than other bonds that have similar characteristics.^h The theme that liquidity attracts liquidity is nicely illustrated by many aspects of the subprime mortgage crisis. For example, interest in trading collateralized debt obligation (CDO) structures has waned partially due to the drying up of liquidity in many such markets—purchasing such instruments became substantially riskier because of the price impact and uncertainty of liquidating positions.ⁱ The breakdown of the auction reset mechanism for municipal bonds is another example of a breakdown of liquidity due to a coordination failure—in this context seemingly rather creditworthy borrowers could not roll over their reset instruments because of doubts about whether the borrower would be able to repay current short-term borrowings due to concerns about the financial status of municipal bond insurers.^j The “seizing up” or “freezing” of interbank lending (“LIBOR”) markets (e.g., in September 2008) is yet another example of how the collapse of liquidity can reflect a coordination failure.

During the spring of 2008, the effective collapse of Bear Stearns was viewed by some as resulting from a liquidity crisis in which the firm’s short-term funding sources dried up because of potential concerns about the firm’s liquidity in the future, spurred at least in part by excess reliance upon such short-term funding sources.^k While a liquidity crisis can occur without

an obvious reason, these also can result in the asset management context from new or renewed concerns about the creditworthiness of a player. The lack of transparency of holdings and even market pricing can heighten concerns about adverse selection and can lead to fragility of an equilibrium in which short-term credit plays a prominent role.^l With the benefit of hindsight, the solvency challenges facing financial institutions in 2008 became more apparent.

The coordination issue also illustrates the difficulty in starting new futures contracts (e.g., the difficulties in attempting to establish the Shiller macroeconomic housing contracts). Often the potential success of instruments is difficult to forecast—which futures instruments will ultimately prove viable and attract sufficient liquidity can be difficult to discern. In this context, it may even make sense for those with a vested interest in the success and viability of the contract to consider subsidizing trading to build up open interest and volume, thereby mitigating concerns about adverse selection and the eventual viability of the contract.

Liquidity and Contract and Market Design

The specification of a contract as well as the market structure in which it trades can influence the underlying liquidity of that instrument. For example, indexed contracts will face less adverse selection than contracts on individual securities because there is much less scope for private information on an indexed instrument.^m The market structure in which an instrument trades also influences the liquidity of the instrument. For concreteness, consider the use of a “call” auction, which aggregates considerable trading activity temporally vs a continuous trading mechanism under which trades are dispersed over time. The continuous mechanism could provide less liquidity than the call auction.

However, not only does the market design influence liquidity, but also the magnitude of potential liquidity can influence the market’s design. A simple real estate example illustrates this point. In selling a unique house with many idiosyncratic features, the use of a broker is likely to be advantageous. Yet in selling a condominium for which there are many substitutes and suitable ways for the seller to reach out to prospective buyers, it need not be optimal to hire a broker. In effect, certain properties are so “attractive”

that they do not need a broker. That a property can potentially be advantageously sold without a broker adds to its *ex ante* value.ⁿ This highlights a potentially important selection difference between the properties sold by brokers and those sold directly; specifically, those being sold through brokers will often be those that are relatively more difficult to sell.

Concluding Comments: The Transmission of Illiquidity

Several major financial market crises also illustrate historically some interesting facets of illiquidity from an asset management perspective. For example, illiquidity can spread across asset categories. This occurred in the Long-Term Capital Management (LTCM) crisis in 1998—part of LTCM’s problems arose from a reluctance to sell instruments that were particularly illiquid because those had the largest losses (by definition). Consequently, the asset sales spilled to more liquid assets in order to reduce leverage. A similar phenomenon in the subprime mortgage crisis caused the spreads to substantially widen for prime jumbo loans and for that market to “freeze.” More broadly, a by-product of the subprime mortgage crisis was the transmission of liquidity problems across both markets and investors around the globe. The resulting contraction in equity capital in turn led to a “credit crunch” and indeed, various actions of the Federal Reserve Board have been an attempt to cushion the resulting economic shocks.

Another example of the interdependence in liquidity was the fallout in September 2008 from the collapse of Lehman Brothers. The subsequent suspension of liquidity by a major money market fund then led to a “run” on money market funds more broadly (temporarily shrinking by about half a trillion dollars)^o and the collapse of the commercial paper market, resulting in both new government guarantee programs to restore “confidence” and a “run” to use open bank credit lines. The various examples in this conclusion illustrate that liquidity is interconnected among assets and can be an aggregate rather than just an asset-specific phenomenon. In fact, historically, at the heart of various financial market breakdowns (including the Great Depression) have been liquidity crises and crises of confidence.

End Notes

^aGlosten and Milgrom [8] provide a second classic treatment of the bid–ask spread under private information and rational expectations.

^bWithin the Kyle [11] model, the structural parameters are constant. The text of the current article describes the comparative static associated with a change in model parameters.

^cThis interpretation of the theorem was originally pointed out by Milton Harris (see [13], p. 21, footnote 3).

^dFor example, these themes are illustrated by Pastor and Stambaugh [14] and Amihud and Mendelson [2].

^eAn interesting recent survey of market microstructure is Biais, Glosten and Spatt [3].

^fThe earliest such studies using high-frequency order data were Biais, Hillion and Spatt [4] and Harris and Hasbrouck [10]. A by-product of distinguishing between quote innovations on both the bid and ask sides of the market in the empirical analysis of Biais *et al.* [4] is that one can potentially distinguish between orders that are motivated by liquidity provision and those that reflect informational trading.

^gDow [7] examines a model with a mix of informed and uninformed traders in which there are multiple equilibria and a tight spread reduces the fraction of informed traders and strengthens the available liquidity.

^hThe nature of the “benchmark bond” in Japan is discussed in Boudoukh and Whitelaw [5].

ⁱChanges in perceived fundamentals also led to reduced interest in CDOs.

^jThis theme is illustrated by Mackenzie [12].

^kSomewhat related to this, even the use of short-term secured repurchase agreements to obtain capital became more restricted because of concerns about potential pricing of the underlying collateral in the event of collapse of Bear Stearns, which was a major securities firm, and concerns about the protection afforded repurchase agreements in the bankruptcy process.

^lCox [6] suggested that the collapse of Bear Stearns resulted from a lack of market confidence in the firm rather than insolvency or the absence of capital.

^mThis theme is explored by Subrahmanyam [15] and Gorton and Pennacchi [9].

ⁿPete Kyle offered an interesting interpretation of this point at the 2007 FDIC conference, noting that when properties are advertised as “one of a kind” that need not enhance their value, since “one-of-a-kind” properties would tend to require greater costs to resell the property efficiently.

^oTo avoid slightly analogous problems that would result from “runs” by their investors, some hedge funds began to utilize “liquidity gates” that limit overall outflows during a redemption period. However, such gates can actually heighten the tendency toward a “run” (e.g., to avoid being shut out).

Execution Costs

Execution costs are the difference in value between an ideal trade and what was actually done. The execution cost of a single, completed trade is typically the difference between the final average trade price, including commissions, fees, and all other costs, and a suitable *benchmark* price representing a hypothetical perfectly executed trade. The sign is taken so that positive cost represents loss of value: buying for a higher price or selling for a lower price. If a trade is not completed either for endogenous reasons (e.g., the price moves away from an acceptable level) or for exogenous reasons (a trader gets sick or a system fails), then some value must be assigned to the unexecuted shares. The cost of a portfolio transaction, or a series of transactions, is computed as a suitably weighted average of the costs of the individual executions.

Some of the costs of trading are direct and predictable, such as broker commissions, taxes, and exchange fees. Although these costs can be significant, they are commonly not included in the quantitative analysis of execution costs. “Indirect” costs include all other sources of price discrepancy, such as limited liquidity (market impact) and price motion due to volatility. These are much more difficult to characterize and measure and are much more amenable to improvement. Since the technology of cost measurement is most advanced for equity trading, we shall use that language; cost measurement for other asset classes is also very interesting, but less developed.

The benchmark is commonly taken to be the *arrival price*, that is, the quoted market price in effect at the time the order was released to the trading desk. Using that benchmark is equivalent to saying that a perfect trade, one with zero execution cost, would be one that executed instantaneously at the arrival price. The cost measured using the arrival price benchmark is called the *implementation shortfall*, a term introduced by Perold [10]: “on paper you transact instantly, costlessly, and in unlimited quantities . . . simply look at the current bid and ask, and consider the deal done at the average of the two.”

For example, suppose that an overnight investment decision assumed that a large quantity of stock could be purchased at the previous day’s closing price of \$50 per share; if the trade was fully completed at

an average price of \$50.25, then the execution cost would be reported as 25 cents per share. However, execution costs are only part of the picture: if the stock closed that day at \$51, then the trade would be successful despite its positive cost; a naïve cost model might assign \$1 profit to the portfolio manager and \$0.25 cost to the trader. Execution costs can be negative, for example, if the price dropped in the course of a purchase program and the asset was acquired for a lower price than that anticipated; or, in the above example, if the benchmark price were the day’s closing price. The forecast execution costs on any particular order typically have a very high degree of uncertainty, due to market volatility and other random effects.

A well-calibrated model for execution costs is an important part of the quantitative investment process. At a minimum, it is a tool for the portfolio manager to evaluate the performance of his or her trading desk and external brokers: were the results achieved on a particular execution compatible with the costs estimated from the pretrade model? Furthermore, anticipated transaction costs should be a component of the portfolio formation decisions: turnover should be minimized, and expected transition costs should be incorporated in the portfolio construction model along with expected alpha. Grinold and Kahn [6] discuss in depth the use of transaction cost models in investment management.

This article is divided into three parts, corresponding to the order in which three aspects should be addressed in designing an investment process, although the order, from the point of view of a single trade, is chronologically the reverse. First, we shall look at posttrade cost reporting, then at optimal trading to minimize execution costs, and finally at pretrade cost estimation.

Posttrade Reporting

“If you can not measure it, you can not improve it,” said Lord Kelvin. The first step toward reducing execution costs in any program is to measure them systematically. For each trade executed, the cost should be reported relative to a collection of benchmarks. In addition, the cost statistics should be computed across all trades in a suitable time period (daily or weekly) and broken down by any relevant parameters: primary market, size of trade, market capitalization of stock, and so on.

As noted above, the most common benchmark is the pretrade arrival price. Another common choice is the “volume-weighted average price” (VWAP), taken across the time interval during which the trade was executed. Although this most likely does not correspond directly to an investment goal, it is a popular benchmark for assessing the quality of the execution, because it largely filters out the effects of volatility. One would typically also use a posttrade price, for example, the closing price on the day during which the trade was executed. Typical posttrade reporting systems display the execution price relative to all of these benchmarks: before, during, and after trading.

When aggregating cost numbers across a diverse variety of trades, the individual cost numbers should be weighted so that the result is representative of the overall change in portfolio value. If the individual costs are measured in cents per share, then they should be weighted using the number of shares in each individual trade. If the individual costs are measured in basis points, then they should be weighted using the dollar value of each trade.

If a pretrade cost model has been developed, then the realized costs should also be compared with the forecast values, both on the level of individual execution, and on the overall portfolio level. This will help to identify trades that may have been badly executed as well as in maintaining accurate calibration of the pretrade model.

In addition to the average, it is useful to report the standard deviation of the costs. This is useful as a reality check for the significance of the mean. For example, if the sample standard deviation were 25 basis points on 100 independent trades, then the expected error in the sample mean would be 2.5 basis points and a change of one or two basis points in the mean cost would not be significant. The standard deviation should also be weighted by trade size; the most reasonable weights are the same that are used for the average cost. The standard deviation does not have good properties under subdivision.

Ideally, aggregate cost numbers would be reported so that the result is indifferent to subdivision of trade blocks, but this is often not possible. For example, suppose that 100 000 shares are purchased throughout the day; a natural benchmark price would be the day’s opening price. However, if this block were considered as 40 000 shares in the morning and 60 000 shares in the afternoon, the arrival price for the second block would be the midday price, and the overall reported

cost would be lower. The choice can be made only with knowledge of the investor’s overall goals. This difficulty does not arise with a VWAP benchmark or with a benchmark price at a fixed time such as at the close.

Additional difficulties in cost reporting come from price limits and incomplete trades. Suppose that a buy order is put in for a stock currently trading at \$50, but a condition is imposed that no shares are to be bought at a price higher than \$50.05. It will then be certain that the price impact on this trade will be at most 5 cents per share, but it may be that only a small fraction of the requested shares are actually executed. If the limit is below the initial price, the situation may be even more extreme. Similar difficulties arise if the trade is halted for other reasons.

The solution to this difficulty rests on the valuation of unexecuted shares, but there is no simple rule. The most straightforward would be to imagine that the unexecuted shares were purchased at the day’s closing price. In practice, this rule is far too stringent and does not take account of the variety of possible reasons the trade might have been halted. Trade cost reporting must take account of the entire investment process.

Optimal Trading

Once a system is in place for measuring and reporting trade costs, and after it has been agreed what criteria define a good trade or collection of trades, then one can design optimal strategies to meet investment goals. “Best execution” is not only advantageous to investors but also is required by regulation in most markets. The most important goal is always to reduce mean execution cost, which is largely due to market impact and uncaptured short-term alpha. One also often desires to reduce the standard deviation of trade costs in order to reduce the overall investment volatility [5].

Reducing costs is achieved by searching for liquidity in “space” as well as in time, accessing as many pools of potential liquidity and as many potential counterparties as possible for each piece of the trade. This includes routing to nonexchange trading venues such as “dark pools” and block crossing services when possible. Rapid changes in market structure make this increasingly complicated (see [7, Appendix] for a discussion of the US equities markets).

Accessing liquidity in time means being willing to slow trading to give potential counterparties the opportunity to appear in the market. If short-term price drift is not expected to be significant, then average trading costs can generally be reduced by trading more slowly.

Other aspects of trading push for rapid trading, most significantly anticipated price drift and market volatility: “To trade a list of stocks efficiently, investors must balance opportunity costs and execution price risk against market impact costs. Trading each stock quickly minimizes lost alpha and price uncertainty due to delay, but impatient trading incurs maximum impact. In contrast, trading more patiently over a longer period reduces market impact but incurs larger opportunity costs and short-term execution price risk” [1]. The actual trade schedule is determined by using a quantitative balance of all of these factors. This schedule may need to be dynamically adapted depending on the observed liquidity or other market components. For a portfolio, correlation between the assets should be included in addition to the volatility of each one, and the schedule may need to maintain strict neutrality to a market index or other risk factors.

In practice, optimal strategies for a mean–variance trade-off, and strategies that are calculated to optimize expected cost in the presence of short-term drift, are generally similar: at the beginning of each execution, rapid trading reduces the exposure to

volatility or alpha, then the trading slows to reduce overall impact costs (Figure 1, from [2]). The most important question is the overall speed of the execution: should it be completed in minutes, hours, or days? Regardless of the model, an approximate quantitative model for execution costs is an essential element of this decision.

Pretrade Cost Estimation

Once a measurement system has run long enough to generate a useful amount of data, one can begin to think about developing an analytic model. The goal of the model is to forecast the execution cost to be expected on any anticipated trade, along with an estimate of the uncertainty in the forecast. In its most general form, such a model must contain a full explanation of how trading in markets affects prices. This is a rich area of research with a large literature (see [9] for an extensive survey; see [4, 8] for more subtle models). Thus, one typically poses the problem in the more prosaic terms of estimating the future in terms of past data.

The goal is to give the predicted cost C (in cents per share or basis points) in terms of input variables, including, at a minimum, the number of shares traded X and the daily volume V of the stock (either historical average or volume on the day of trading), and the effective duration T over which the trade was executed as in Figure 1. To normalize across many different stocks, one should also include properties such as volatility σ , and, perhaps, market capitalization, primary exchange or country, and other economic parameters. In addition, one might include trade information such as the anticipated short-term alpha, and the algorithm or other means that were used to trade the stock.

For any proposed trade, the pretrade model predicts the cost on the basis of cost that was measured on “similar” trades in the past. “Supervised learning” algorithms [11] could, in theory, be used to carry out this classification. In practice, because the dimension of the parameter space is so large, there may be no, or very few, trades that are sufficiently similar to the proposed ones in all variables. This argues for a regression approach in which a specific functional form is proposed, calibrated to data, and evaluated using standard statistical tests of significance.

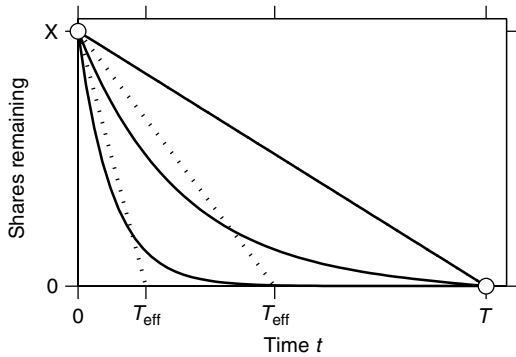

Figure 1 Optimal trading trajectories with varying degrees of urgency (solid curves). Regardless of the exact analytic form of the curve, the most important variable is the approximate effective duration T_{eff} corresponding to a linear approximation of the trajectory and represented here by a broken line

The most detailed of such a study was carried out by Almgren *et al.* [3]. This model is based on separation of the cost into a “permanent” and a “temporary” component. Although both components contribute to the realized cost on every trade, it is useful to calibrate each separately. The calibration relies on three observed prices: (i) S_{pre} denotes the arrival price, that is, a market price just before the order begins trading; typically, this would be the bid–ask midpoint before the first execution; (ii) S_{exec} is the actual average price for which the order finally executes, which is, of course, the quantity of most interest to the trader; and (iii) S_{post} denotes a market price just after the order has finished executing, possibly with a short time lag to allow transient effects to dissipate.

The model of Almgren *et al.* [3] measures two quantities I and J , for permanent and temporary impact, respectively. For a buy order, these are

$$I = \log \frac{S_{\text{post}}}{S_{\text{pre}}} \approx \frac{S_{\text{post}} - S_{\text{pre}}}{S_{\text{pre}}} \quad (1)$$

$$J = \log \frac{S_{\text{exec}}}{S_{\text{pre}}} \approx \frac{S_{\text{exec}} - S_{\text{pre}}}{S_{\text{pre}}} \quad (2)$$

and for a sell order, the signs would be reversed. The approximate equalities are valid for moderate-sized orders, for which the price does not move more than a few percent during execution. These quantities represent price changes relative to the pretrade price, as fractions of that benchmark.

The permanent component of cost is interpreted as the net displacement of the market due to the buy–sell imbalance introduced by this particular trade. The simplest model sets

$$I = \gamma \sigma \frac{X}{V} + \langle \text{noise} \rangle \quad (3)$$

In this expression, we normalize the trade size X by the day’s volume V , so X/V is the trade size as a fraction of a typical day’s flow. We also normalize the impact I by the volatility σ , so that we represent the impact as a fraction of a typical amount that the stock moves without our trading. The coefficient γ is taken to be constant across all stocks, with widely varying daily volumes and volatilities. The noise term arises from intraday volatility: the actual cost experienced on any particular trade may be very different from the mean prediction from the model.

In this form of the model, the permanent impact is linear in the total number of shares traded. This model is particularly convenient for theoretical modeling but must be justified by empirical analysis of real-trade data. Almgren *et al.* [3] found a reasonable agreement with their data, but other recent empirical studies have suggested that the linear form might not be justified.

The temporary impact component of cost is interpreted as the additional premium that must be paid for execution in a finite time, above a suitably prorated fraction of the permanent cost. We model it as

$$J = \frac{I}{2} + \eta \sigma \left(\frac{X}{VT} \right)^\beta + \langle \text{noise} \rangle \quad (4)$$

where T represents the effective duration of the trade as a fraction of the trading day. Thus, X/VT represents the “participation rate” or the fraction of market flow that this trade constitutes during the time that it is active. The factor $1/2$ on the permanent cost component represents the fraction of posttrade impact that is paid on the trade itself. As for the permanent cost, the impact cost is expressed as a fraction of typical volatility; the coefficient η is taken constant across all stocks. Other factors such as bid–ask spread and market capitalization were not determined to be significant in US equity markets.

Almgren *et al.* [3] calibrate this model to a large sample of the US equity trades using a two-step procedure. First, the permanent impact term I is calibrated, testing the hypothesis of linear impact and estimating the value of γ . Next, the temporary impact term J is calibrated, determining values for the exponent β and the coefficient η . A key aspect of the verification is characterization of the error terms to verify that volatility is an adequate explanation for the residuals. The result has $\beta \approx 0.6$, which is roughly compatible with the earlier square-root models [12], as well as values for the coefficients γ and η . For trades that are a few percent of daily volume executed across several hours, the predicted impact costs are tens of basis points.

A number of factors make such models at best very approximate. The first is the extremely low values of R^2 in the regression, typically around a few percent at best. That is, the ability of the model to predict the cost of any single trade is very poor, because market volatility due to other trading activity is usually very large. The second, is

the difficulty of the model in distinguishing market impact from alpha: did the price move up because the buy program impacted the price or was the trade executed because the manager correctly anticipated a price rise? A third difficulty is difference in behavior between small and large trades: although the model claims to be universally valid, in practice, a model developed for small trades gives poor results on large trades.

In any particular application, the model should be critically evaluated by the user and recalibrated and extended as necessary. Despite its intrinsic difficulties and limitations, this model and extensions are extremely useful to give approximate anticipated cost values for pretrade planning, optimal trade scheduling, and posttrade evaluation.

ROBERT ALMGREN

Bid-Ask Spreads

The literature on asset pricing often assumes an ideal world where security prices are set by market participants in *frictionless* financial markets. However, a variety of market frictions, including trading costs and constraints on short selling, exist in actual markets. It is important for market participants to accurately estimate and incorporate the impact of trading costs. For portfolio managers and investors, implementing investment decisions is costly and will typically lead to a shortfall in investment performance [26] relative to that theoretically attainable in frictionless markets. Decisions need to be conditioned not only on the fundamental soundness of potential investments but also on the anticipated costs of implementing the required trades. Estimates of trading costs also serve as a measure of market quality, allowing policy makers to assess the impact of regulatory reforms and exchange officials to assess the effects of trading rule and market structure changes, and informing corporate managers' decisions on where to list their shares. This article provides an overview of several issues related to measuring trading costs in financial markets. It focuses on three related measures of trading costs: quoted spreads, effective spreads, and realized spreads.

The Nature of Trading Costs

A fundamental issue in trading is the asynchronous arrival of buyers and sellers [9]. This creates uncertainty as to the amount of time that will be required to locate a counterparty, and regarding the market price that will prevail at the time a trading partner is located. This uncertainty can be mitigated by the continual presence of "liquidity suppliers", who stand ready to serve as counterparties, thereby providing immediacy of trade execution, that is, "liquidity". Liquidity suppliers often take the form of designated market makers or dealers, but liquidity can also be provided by traders in the form of limit orders.

Liquidity providers need to be compensated for the costs involved. Besides order processing costs, dealers incur inventory holding and adverse selection costs. Accommodating investors' order flows generally leaves dealers holding inventory positions that are not optimal in terms of the diversification of risk

[16] (see **Inventory Effects**). Further, dealers need to be compensated for the possibility that some buy or sell orders can originate with traders possessing superior information regarding security value. Dealers, on average, lose money on transactions with better-informed traders [13, 22] (see **Glosten-Milgrom Models; Kyle Model**), who sell to dealers ahead of price declines and buy from dealers ahead of price increases.

Dealers recover these costs by purchasing at a lower "bid" price, while selling at a higher "ask" (or "offer") price. The bid and ask prices are the dealer's quoted prices or "quotes", and the difference between the two is the bid-ask or quoted spread, a measure of trading cost. The corresponding quantities offered by the dealers at the quoted prices are referred to as the *quoted depth*, that is, the *bid depth* and the *ask depth*.

In most financial markets, including the New York Stock Exchange (NYSE) and the Nasdaq Stock Market, liquidity provision by designated dealers is augmented by standing limit orders submitted by public traders. A limit order to buy sets a maximum price to be paid, while a limit order to sell sets a minimum price that will be accepted. A limit order may be viewed as a one-sided quote. Some markets (e.g., The Hong Kong Stock Exchange) operate without designated dealers, in which case, the bid-ask spread is determined by the most aggressively priced unexecuted limit orders. In summary, the bid-ask spread, which measures trading costs for investors buying at the ask and selling at the bid, arises to compensate liquidity providers for order processing, inventory, and adverse selection costs.

Measures of Trading Cost

To estimate trading costs, empirical methodologies rely on the simple intuition that transactions would occur at the true underlying security value in the absence of trading costs. Hence, the deviation between transaction price and an estimate of the true underlying security value is an estimate of trading cost. For buyer (seller) initiated trades, the traded price is expected to be higher (lower) than the true security value, the difference being the estimate of trading cost.

The Quoted Spread

The simplest measure of trading cost is the quoted spread (QS), which is defined as the difference between the bid and ask prices. The quoted spread measures the cost of completing a round trip (buy and sell), if trades are executed at the quoted prices. Execution costs for a single trade are often measured as half the spread, described on a percentage basis by equation (1):

$$\text{Quoted half spread} = QS_{it} = 100 \times \frac{(A_{it} - B_{it})}{(2 \times M_{it})} \quad (1)$$

where A_{it} and B_{it} are the posted ask price and bid price for security i at time t , respectively, and M_{it} , the quote midpoint or mean of A_{it} and B_{it} , is a proxy for the true underlying security value.

The Effective Spread

In many dealer markets, including those that trade fixed-income securities and foreign exchange, the quoted prices are simply a starting point for negotiations between customers and dealers, and transactions frequently occur at prices other than the quotes. Also, in some markets, including those relying on trading floors, there may be *latent liquidity* not reflected in the quotes. On the NYSE, for example, market orders may execute at prices within the quotes when the specialist (the NYSE's designated dealer) or a floor broker elects to improve on the quote [28, 30] (see **Specialist Markets**). Many electronic exchanges allow traders to hide some or all of the order size, implying that limit orders offering more attractive prices than the quotes may exist on the book [4] (see **Order Types**). Further, quoted prices pertain only to the quoted depth; large orders might exhaust the depth at the quote and "walk up the book", executing against limit orders with less attractive prices and leading to a weighted-average trade price outside the quotes.

When trades occur either within or outside the quotes, a better measure of trading costs is the percentage effective half spread, which is based on the actual trade price, and is computed on a percentage basis as described in equation (2):

$$\text{Effective half spread} = ES_{it} = 100 \times D_{it} \times \frac{(P_{it} - V_{it})}{V_{it}} \quad (2)$$

where P_{it} is the transaction price for security i at time t , D_{it} is an indicator variable that equals 1 for customer buy orders and -1 for customer sell orders, and V_{it} is an observable proxy for the true underlying value of security i at time t . The effective spread is based on the deviation between the execution price and the true underlying value of the security, and can be viewed as an estimate of the execution cost actually paid by the trader and the gross revenue earned by the liquidity provider.

It is also possible to distinguish between the noninformational (inventory and order processing) and informational (adverse selection) components of trading costs, on the basis of the behavior of prices *subsequent* to a transaction. The seminal paper using this approach is [21]. The intuition is that noninformational transaction costs should result only in a *temporary* deviation of price from value, evidenced by a price reversal after the trade. In other words, while customer purchases (sales) should occur at prices above (below) pretrade value, we should subsequently observe a partial reversal of the price change. The price reversal is partial rather than full because the informational component of trading costs is, on average, associated with a *permanent* increase (decrease) in security value after buys (sells). The informational component can be measured by the change in the estimate of security value, while the noninformational component can be measured by the reversal from trade price to posttrade value.

Estimating the Informational Component: The Price Impact of Trades

The possible presence of informed traders is revealed to liquidity providers in a noisy manner by the order flow imbalance, that is, the difference between quantities of buy *versus* sell orders, which will tend to be positive when the security is undervalued and negative when the security is overvalued. Market makers incorporate the information in order flow imbalances by adjusting quotes upward (downward) after buy (sell) orders. These price adjustments reflect both the proportion of the informed traders *versus* liquidity traders in the market, and the extent of superior information about security value held by the informed traders. The private information contained in trades, or equivalently the amount of adverse selection cost incurred by the liquidity provider, can

be estimated using equation (3):

$$\text{Price impact of trade} = PI_{it} = 100 \times D_{it} \times \frac{(V_{it+n} - V_{it})}{V_{it}} \quad (3)$$

where V_{it+n} denotes the security's true underlying value n periods after the transaction. The price adjustment from V_{it} to V_{it+n} reflects the markets' assessment of the private information conveyed by the trade [3, 17] (see **Price Impact**). Research has documented that markets are particularly sensitive to order flow imbalances ahead of anticipated news disclosures, such as earnings announcements by corporations [23], as price impacts are larger than on nonannouncement days. The price impact of trades is an often used empirical proxy in the corporate finance literature for the degree of information asymmetry regarding security value across traders.

Estimating the Noninformational Component: Realized Spreads

The presence of informed traders will cause market prices, on average, to rise after customer buys and to fall after customer sells. Owing to these adverse price movements, market makers earn less than the effective spreads for their services. Market making revenue net of losses to better-informed traders can be measured by the *reversal* from the trade price to the posttrade value. The realized spread captures the extent of reversal, computed using equation (4):

$$\begin{aligned} \text{Realized spread} = RS_{it} &= 100 \times D_{it} \times \frac{(P_{it} - V_{it+n})}{V_{it}} \\ &= \text{Effective Spread}_{it} - \text{Price Impact}_{it} \end{aligned} \quad (4)$$

As noted above, some studies refer to price impact and realized spreads as the “permanent” and “temporary” price impacts of a trade [21, 25]. Some authors [29] have argued that trading costs and market quality are better measured by temporary price impacts (realized spreads) than by total price impacts (effective spreads).

Implementation Issues

To measure effective or realized spreads, researchers need to identify (i) whether the trade was initiated

by a buyer or a seller, and (ii) estimates of security value before and after the trade. As documented in recent research, the methodological choices regarding these issues are nontrivial and can significantly affect estimates of trade execution costs [27, 32].

Algorithms for Assigning Trade Direction

Some publicly available databases from international markets, for example, Euronext-Paris and the Toronto Stock Exchange, as well as some proprietary datasets on institutional trading, for example, those provided by consulting firms Abel/Noser or Plexus, contain information on the buy and sell orders submitted to the markets. In contrast, databases such as Trade and Quote (TAQ) (released by the NYSE) and Nastraq (released by Nasdaq), which are widely studied owing to their comprehensive inclusion of all trade and quote data for all listed US stocks, do not provide information on underlying buy and sell orders. As a consequence, the direction of the trade (i.e., whether the trade was initiated by a buyer or a seller) must be imperfectly inferred from the available data (see [2] for a detailed discussion).

In datasets where order level data is not available, the most widely used algorithm for assigning trade direction is that recommended by Lee and Ready [24]. Their algorithm assigns trades completed at prices above (below) the prevailing quote midpoint as buyer (seller) initiated trades. Trades executed at the quote midpoint are classified on the basis of a “tick test”. The tick test assigns a trade as a buy (sell) if the trade executes at a higher (lower) price as compared to the most recent trade at a different price. An alternative algorithm is proposed by Ellis, Michaely and O'Hara [11], who assign trades executed at the ask (bid) quote as buyer (seller) initiated, while using the tick test for all other trades. On the basis of proprietary order level data, prior research finds that the algorithm proposed by Lee and Ready [24] works fairly well, classifying about 85% of the trades correctly.^a Error rates are slightly lower for the algorithm proposed by Ellis, Michaely and O'Hara [11] (see [2] and [12]).

Research based on data from the early 1990s [14] finds that trade report times lagged actual trade times for NYSE stocks. As a consequence, studies such as [24] recommend adjusting the time stamps by 5 s when comparing trades and quotes. However, for recent data, Bessembinder [2] and Ellis, Michaely and

O'Hara [11] report that the allowance for reporting lags is not necessary. They recommend that trades are best compared to contemporaneous quotations for both NYSE and Nasdaq stocks when assigning trades as buyer or seller initiated.

Pretrade Benchmark Price

Pretrade price impact refers to implicit trading costs that may be incurred if prices move systematically away from the trader (rising before buys or dropping before sells) between the time of a trade decision and complete execution of the order [26]. Pretrade price impact will tend to arise when larger orders are broken into smaller orders and executed successively. Prices may also move away from a trader because his trading intentions are detected by market participants who then "front run" the order or engage in "predatory trading" [7], or simply infer information from the existence of the trading interest. In addition, prices will tend to move away from traders relying on momentum strategies. Executing a trading program too slowly exposes traders to the risk of larger pretrade price impacts. On the other hand, executing orders that are larger than quote sizes too quickly may result in larger effective spreads. The skill of a trader handling larger orders lies in balancing these effects. To capture the impact of trader's "timing" and "liquidity" decisions, Perold [26] recommends that the average of the prevailing bid and ask quote at the time of the trading decision be used as the pretrade benchmark price.

However, data on trade decision times is often not available, except in specialized proprietary datasets such as that studied by Conrad, Johnson and Wahal [8]. Studies using publicly available datasets, including [17] and [3] use the quote midpoint at the time of the trade as the pretrade benchmark price. Although adverse drift in prices ahead of trade executions is most obviously an issue for larger traders, recent evidence [2, 27, 32] indicates that prices move systematically and adversely in the seconds before even small trades are executed. Bessembinder [2] recommends that researchers use quotation midpoints in effect 5 s prior to the trade report time as a proxy for the true underlying price (V_{it}) when measuring effective spreads and price impact of trades.

Posttrade Benchmark Price

The posttrade benchmark price (V_{it+n}) should be measured when the market has had sufficient time to incorporate the information contained in the trade [17]. If the period after the trade time is too short, temporary price effects may still dominate, or alternately, the market may not have had a chance to assess the trade's likely information content. If the period is too long, the measure will become unnecessarily noisy because of the arrival of extraneous information. In the absence of theoretical guidance, studies have used different proxies for the posttrade benchmark price. Studies using institutional data have often used the closing price on the day of trade as the posttrade price [20]. The practitioner literature commonly relies on the volume weighted average price (VWAP) on the day of the trade. Among datasets with broad coverage, Huang and Stoll [17] use the first trade price both 5 and 30 min after the trade, while Bessembinder and Kaufman [3] use the quote midpoint 30 min and 24 h after the trade. Bessembinder [2] used the midquote in effect 30 min after the time of the reference quote, or the 4 p.m.-quotation for trades completed during the last half hour of trading. Werner [32] reports that realized spread measures obtained in large samples are relatively insensitive to the choice of the posttrade benchmark price.

Since September 2001, the Securities and Exchange Commission (SEC) has required each US stock "market center" to compile and disseminate on a monthly basis various standardized measures of execution quality in nearly all publicly traded securities [6]. The intent of SEC Rule 605 (formerly 11Ac1-5) is to provide traders with information on execution quality at different market centers. The execution quality measures that each market now reports include round-trip effective spreads, realized spreads, as well as average execution speed. The regulation provides something of an official validation of the effective spread and realized spread measures described above, and also codifies a specific methodology to estimate trading costs based on the order level data available to each market center. Specifically, the effective spread compares the traded price to the quote midpoint (as a proxy for V_{it}) at order arrival, while the realized spread is based on the quote midpoint (as a proxy for V_{it+n}) 5 min after the trade.

Evidence on Trading Costs

Jones [19] provides a detailed perspective on trading cost in US markets over the last century. He estimates that quoted spreads on Dow Jones stocks were in the range of 0.60% for sustained periods until the beginning of 1980s, with spikes in spreads observed during market downturns, such as the Great Depression. He documents that during the last two decades trading costs have fallen dramatically to around 0.20% for Dow stocks, partly facilitated by regulation but mainly by increased competition among market centers with the onset of electronic trading systems (see [15] for recent evidence).

Several recent studies have examined execution quality for comparable firms on the two major US market centers—the NYSE and the Nasdaq. In 2001, subsequent to regulatory changes, Bessembinder [1] reports that effective spreads are similar for comparable firms in the two markets. The most recent evidence available appears to be that reported Boehmer [6], using Rule 605 data over November 2001 to December 2003; he reports an average effective spread for NYSE stocks of 6.2 cents per share, *versus* 8.8 cents for comparable Nasdaq stocks.

Several studies have examined execution quality in market outside the United States. For example, Venkataraman [31] reports that effective spread for large firms traded on the Paris Bourse were 0.25% in 1997, relative to 0.21% for comparable firms on NYSE. Jain [18] reports on trading costs during the year 2000 for liquid firms on 51 stock exchanges around the world. The average effective (realized) spread across exchanges is 2.13% (2.15%). However, there is considerable variation in effective (realized) spreads across markets, ranging from 0.10% (0.25%) at the NYSE (Luxembourg) to 14.47% (14.6%) in Ukraine. Research indicates that differences in execution quality across markets are related to both exchange-design features, such as tick size and order handling rules, and the regulatory environment, such as the enforcement of insider trading laws and the protection of shareholder rights [5, 10].

Conclusions

Trade execution costs, which reflect the price concessions necessary to complete transactions quickly, are

important indicators of market quality and important determinants of traders' actual investment results. Execution costs arise because it is costly to provide liquidity, including order processing costs, inventory holding costs, and losses suffered to better-informed traders. Trading costs can be estimated on the basis of comparisons of trade prices with proxies for underlying security value, the most common proxy being quote midpoints. Comparisons can be of trade prices to midpoints at or before the time of the trade, as in effective spread measures, or to midpoints after the trade, as in realized spread measures. Further, the amount of asymmetric information present in a market can be estimated by assessing trades' price impact, measured as the difference between post- and pretrade estimates of security value. Recent research indicates that trade execution costs have declined steadily in US markets in recent years, particularly subsequent to decimalization in 2001, and documents substantial variation in average trading costs across international equity markets.

Acknowledgments

We would like to thank Charles Jones for his comments.

End Notes

^a. However, the accuracy of the algorithms in postdecimalization data, which is characterized by substantial increases in the number of quote revisions and trades, has, to our knowledge, not been assessed.

Liquidity Premium

An asset is liquid if it can be traded quickly and at low cost. In addition to risk, liquidity affects asset prices and returns. Because investors want to be compensated for bearing the costs of illiquidity, *asset returns are increasing in illiquidity*. Thus, asset prices should depend on two asset characteristics: risk and liquidity.

Illiquidity reflects the costs of executing a transaction in the capital markets. These costs include three components:

1. *Price-impact costs* reflect the price concession that a buyer or seller makes when trading, or the price of immediacy: a discount when selling or a premium when buying. For small orders, the market impact is confined to the *bid-ask spread* (“spread”), which is the difference between the buying and selling price currently quoted by dealers or market-makers. For large orders, the price impact exceeds the spread and generally increases in the order size. *Depth* is the largest order size for which the price-impact cost is confined to the bid-ask spread.
2. *Search and delay costs* are incurred when a trader searches for better prices than those quoted in the market or wishes to reduce the price impact of his/her order. This often occurs with block orders, where traders prefer to search for counterparties rather than “dump” the entire order on the market. While reducing price-impact costs, the trader bears search and delay costs because the trade is not executed immediately. In particular, the trader incurs opportunity costs and risk while holding the position as the order awaits execution. For example, for a trader who wishes to sell a stock, its price may decline while he/she is searching for a counterparty. The trader then trades off the benefit of a lower price-impact cost against the risk of the market turning against him/her.
3. *Direct trading costs* include exchange fees, taxes, and brokerage commissions. These are also subject to trade-offs: For example, a trader may ask a dealer to liquidate a block, with the dealer bearing the search and delay cost while the trader pays a larger commission.

The three components of transaction costs are highly correlated: Assets with high price-impact costs or high bid-ask spread often have high search and delay costs and high brokerage commissions. Other measures of liquidity are correlated with these three components. For example, more liquid stocks (by the above measures) usually have greater turnover or trading volume and larger market capitalization.

How Does Liquidity Affect Asset Prices?

We have developed a model that shows how liquidity affects asset prices [4]. The model characterizes assets by their transaction costs and investors by their investment horizons. Each investor maximizes the expected present value of the cash flows that his/her assets generate considering the costs of transacting. In equilibrium, the return on an asset is an increasing function of its illiquidity costs because investors require a compensation for bearing these costs. The relation between illiquidity and return is increasing and concave, that is, the increase in return is mitigated for less liquid assets, which are held by investors with longer investment horizons who can depreciate their transaction costs over a longer period of time. The positive effect of illiquidity on stock returns is more prominent for liquid assets, which trade—and hence bear the transaction costs—more frequently.

Although the illiquidity costs of a single transaction are low relative to the asset price (for most publicly traded securities, they are a fraction of a percent), their *cumulative* effect on value is large because they are incurred repeatedly over the security’s life. Thus, the impact of illiquidity costs should equal *at least* the present value of all costs incurred currently and in the future, which can be substantial relative to the value of a stock, whose life is infinite. Further, less liquid securities produce in equilibrium higher after-transaction-costs (net) returns to long-term investors. Higher returns are necessary to induce long-term investors to hold illiquid securities rather than compete with short-term investors for the more liquid securities.

We present empirical evidence on the effects of liquidity on asset prices and expected returns. For stocks, bonds, and other financial instruments, the lower the liquidity, the higher the return or the lower the price (after controlling for other characteristics, such as risk). The evidence further shows that risk-averse investors price illiquidity risk.

Liquidity and Stock Returns

We tested the return–illiquidity relationship on NYSE-AMEX stocks during 1960–1980 [4, 6]. We divided stocks into seven portfolios by their spread, a common measure of illiquidity, and into seven portfolios based on their β coefficient, the capital asset pricing model (CAPM)-based measure of risk, amounting to a total of 49 (7×7) portfolios. In a cross-sectional estimation of the average return on each portfolio as a function of the spread and unsystematic risk, we found that average portfolio returns were significantly higher for stocks with higher spreads. The function was increasing and concave, as predicted by our model. The following formula and chart summarize our results:

$$R_j = 0.0065 + 0.0010\beta_j + 0.0021 \ln(S_j) \quad (1)$$

where R_j is the return on portfolio j and S_j is the spread (as a fraction of price). To illustrate, increasing the spread from 1% to 2% increased the average monthly return by 0.3% ($= 0.21 \cdot \ln(2)$) or about 3.6% per annum. The spread effect remained significant after controlling for firm size.

Subsequent studies support the theory that higher illiquidity entails higher expected returns, after controlling for risk and other characteristics, using a number of alternative measures of liquidity. Brennan and Subramanyam [13] use each stock's price-impact cost (per unit of order size) as well as the fixed cost associated with the spread, finding a strong positive relationship between average stock returns and both measures of illiquidity. Datar *et al.* [17] measure liquidity using stock turnover (the ratio of trading volume to shares outstanding), and [12] use trading volume to measure liquidity. Both studies find that the higher the liquidity, the lower the stock's return after controlling for risk and other characteristics. This relationship, which is consistent with the theory, is found to be very robust.

The illiquidity discount is evident in the pricing of restricted stock, that is, stocks with trading restrictions^a issued by companies that already have identical stocks traded in the public market. Thus, we observe two securities—the publicly traded stock and the same-company restricted stock—with the only difference between them being their liquidity. Consistent with the theory, Silber [21] finds that the average price of the restricted stock is 34% lower than that of the corresponding publicly traded

stock (after controlling for size, earnings, and the relationship between the restricted stockholders and the company).

Liquidity and Bond Yields

We tested the liquidity effect by examining the differences between US Treasury bills and notes with less than six months to maturity [7]. For these maturities, both securities are discount instruments and when maturities are matched, they are completely identical, except that Treasury bills are much more liquid than notes. The average spread on bills in our sample is 0.00775% compared to 0.0303% for notes. The brokerage fees are \$12.5–\$25 per \$1 000 000 value for bills and \$78.125 per \$1 000 000 for notes. Similarly, notes have a higher price-impact cost than bills. Because notes are less liquid than bills with the same maturity, our theory predicts that their yields should be higher. We tested the liquidity effect for 37 randomly selected days between April and November of 1987, analyzing 489 matches of notes and bills with the same maturities. As predicted, we found that the annual yield to maturity on notes was 0.43% higher than on bills with the same maturity. Kamara [18] finds that the note–bill yield differential holds after controlling for a number of security characteristics. A similar pattern is observed in the bond market in the yield differential between on-the-run bonds, which are most recently issued, and their less liquid off-the-run counterparts, whose maturity is only slightly shorter since they were issued earlier. A number of studies document a lower yield to maturity for on-the-run bonds compared to their off-the-run counterpart [19, 22]. In addition, the note–bill yield spread can be viewed as the difference between off- and on-the-run securities.

Corporate bonds have higher yields than similar-maturity Government bonds, and within corporate bonds, lower rated bonds have yet higher yields. This yield differential has traditionally been attributed to differences in the risk of default, which is surely higher for corporate bonds and yet higher for lower rated bonds. However, if illiquidity costs are higher on corporate bonds and on riskier bonds, part of the yield differential is due to illiquidity. This issue is studied by Chen *et al.* [16]. They estimate the illiquidity cost of corporate bonds and find that it generally increases as the bond rating declines. Then,

they estimate the effect of illiquidity on bond yields across bonds, controlling for risk, issuer characteristics, and the bond's special features. They find that illiquidity has a strong positive and robust effect on bond yields. Further, *changes* in bonds' illiquidity costs lead to changes in bond yields, as predicted. In the United States, Rule 144A bonds, which are less liquid corporate bonds whose trading is restricted to "qualified investors," exhibit a significant discount. Chaplinsky and Ramchand [15] find that the yield on Rule 144A bonds is 0.49% higher than on unrestricted bonds with similar characteristics. The differential is particularly large for investment-grade bonds.

Liquidity Changes Over Time and Liquidity Risk

Just as liquidity affects asset prices across securities, liquidity *changes* over time bring about *changes* in asset prices. One example is the October 19, 1987 stock market crash in the United States. Amihud *et al.* [11] propose that the crash resulted partly from a decline in investors' perception of the overall market liquidity compared to the precrash level. Consequently, investors priced securities lower, which led to the crash. Studying NYSE stocks in the S&P 500 list, they find that on October 19th, the dollar spread increased by more than 63% compared to its precrash level, and the quoted depth also declined significantly. The sharp decline in market liquidity followed a period when investors had believed the market could absorb large order flows with a small effect on prices. The study finds that across stocks, those whose price declined the most on the crash day were those with the greatest deterioration in liquidity, and the stocks that recovered most by the end of October 1987 were those whose liquidity improved the most.

Stock liquidity changes when a market trading system is improved. Around the world, markets have been moving from daily call-auction trading to more liquid, higher frequency trading. Amihud *et al.* [9] study the effect of moving stocks in the Israeli stock market from once-a-day call auction to a higher frequency trading regime. They show that stocks that moved to the improved trading system enjoyed greater liquidity (greater turnover and lower volatility-to-volume ratio) as well as a sharp increase in value of at least 6%. Subsequent studies obtain

similar results for other markets that improved their trading systems and became more liquid.

Market liquidity changes not only in response to singular events but also over time for economic reasons. The question that arises is whether this affects stock prices over time. Amihud [2] finds that when market illiquidity rises unexpectedly, stock prices fall and subsequent expected return rises, consistent with our theory. The effect of liquidity shocks on realized current returns and on subsequent expected return is particularly strong for small, illiquid stocks, because of a "flight to liquidity," namely, to larger stocks that are less vulnerable to liquidity shocks.

It follows that for risk-averse investors, a security's *liquidity risk*, measured by the exposure of its value to liquidity shocks, should affect its price and expected return. Pastor and Stambaugh [20] and Acharya and Pedersen [1] find that stocks whose return is more sensitive to market illiquidity shocks have, on average, higher average return (controlling for other stock characteristics). In addition, Acharya and Pedersen find that, within a CAPM model that allows for liquidity risk, higher sensitivity of stock illiquidity to market illiquidity as well as higher sensitivity of stock illiquidity to the market return also bring about higher expected stock returns. That is, systematic liquidity^b risk is priced.

Some Investment Implications

The theory and empirical results suggest that liquidity is priced: for any given level of risk, more illiquid securities have lower price or higher expected return or yield. Risk, too, lowers securities' prices, but there is a large difference between what investors can do to mitigate the costs of risk and illiquidity. To reduce risk, investors can diversify their holdings. Since most of securities' risk is idiosyncratic (uncorrelated across securities), a diversified portfolio enables investors to get rid of most of the risk, exposing investors only to systematic, diversifiable risk. And, while the total economy's risk is not diversifiable, an investor can hedge the market risk using appropriate market instruments (e.g., derivatives). In contrast, the cost of illiquidity cannot be diversified away. It is additive, so a portfolio of illiquid stock remains illiquid. Still, illiquidity can be managed by constructing a portfolio of securities with

different liquidity, ranging from cash-equivalents (the most liquid) to small, infrequently traded stocks and bonds. The objective is to reduce the frequency of trading in the least-liquid securities, thus enjoying their higher return while not bearing the full cost. Instruments that deal with the lower liquidity of small or risky stocks are closed-end funds and exchange-traded funds (ETFs) of such stocks. Trading these relatively traded funds absolves the trader from bearing the higher transaction costs of the underlying stocks. Consistent with the theory, Chan *et al.* [14] find that liquid closed-end funds of countries with low-liquidity stocks trade at a premium (or lower discount).

Asset managers usually focus on stock selection and market timing. However, the manager's skill in buying and selling the positions they manage has a substantial effect on fund performance. In particular, managing the trading so as to minimize transaction costs helps improve fund performance. For example, an alternative to a sale of a large quantity of shares may be to split the order and sell it in pieces in a way that provides an optimal trade-off between lowering the cost of trading and increasing the risk that results from spreading the execution over time.

Because systematic liquidity risk is also priced in addition to the ordinary CAPM β , portfolio optimization must take this risk into account. As transaction costs affect the *net return* on stocks, reducing the risk of net portfolio return calls for portfolio strategies that reduce the exposure of the stock's return and liquidity costs to the market return and to market liquidity shocks.

Some Corporate Finance Implications

The effect of liquidity on the return required by investors means that a company can reduce its cost of capital by increasing the liquidity of its stocks or bonds. The company can thus increase its market value for any given cash flows that it generates, by employing liquidity-enhancing strategies. We suggested [5, 8] a number of such strategies. One strategy is increasing the company's investor base, especially by adding small individual investors, increases liquidity and raises the stock price. Amihud *et al.* [10] find that when Japanese companies made their stocks more accessible to small investors by reducing the minimum trading unit, their investor bases increased,

resulting in an increase in stock liquidity and price. In general, the investor base can be increased by making it easier to trade the company's stocks and bonds (e.g., inducing more dealers to make a market in the company's bonds) and advertising the company so that individual investors are familiar with it.

Liquidity is also enhanced by providing voluntarily more information about the company, since it reduces the asymmetry of information about its value. This can be done by providing transparent financial reporting, making prompt announcements of new information, and facilitating the provision of information to the public, for example, through analysts.

Liquidity is also improved by reducing fragmentation in trading the stocks and bonds of a company. Amihud *et al.* [3] find that when two virtually identical securities are traded in the market—in that case, stock and deep-in-the-money warrants of the same company—the stock's value rises when the warrant is exercised, which eliminates fragmentation and makes the stock more liquid (since its outstanding value increases). In general, the larger the stock or bond issue, the greater its liquidity and the higher its value. This means that the benefits of having multiple classes of stock or small series of bonds should be considered against the resulting reduced liquidity, which raises the corporate cost of capital.

Concluding Remarks

Expected asset returns depend on their liquidity (or marketability) in addition to risk. For both bonds and stocks, the less liquid the asset, the higher its return (after controlling for risk). Further, the effects of liquidity on asset values and returns are larger than one might naively expect, because the costs of illiquidity are incurred repeatedly, whenever the asset is traded.

These results have important implications for investments, corporate financial decisions, and public policy. Securities analysis should incorporate, in addition to cash flows and risk considerations, the liquidity of the security and possible changes in it. Trading and portfolio construction strategies should incorporate liquidity considerations. Companies that issue securities should opt to enhance their liquidity in order to increase their price. And companies should employ strategies that make their publicly traded securities more liquid. Finally, there is value in public

policy that increases market liquidity, which reduces the corporate cost of capital and improves overall economic performance.

End Notes

^aTypically, restricted stock cannot be traded in the public markets over a period of one or two years.

^bAcharya and Pedersen [1] use three liquidity β s to measure systematic liquidity risk, and show these β s are priced.

Adverse Selection

Adverse selection is potentially an important issue in a financial market whenever any trader has private information related to the value of an asset. An informed trader will strategically adjust his or her trade across states in a manner that reduces the payoff of an uninformed counterparty. The latter is subject to adverse selection: the likelihood of a transaction increases precisely in those states of the world in which the payoff from the transaction is lower.

Adverse Selection in Quote-driven Markets

Consider a single-period binomial model for one stock. In standard fashion, at time 1, the value of the stock is v_h with probability π and v_ℓ with probability $(1 - \pi)$ (see Figure 1). Suppose the risk-free rate is normalized to zero. Then, at time 0, a risk-neutral agent is indifferent between buying and selling any quantity of the stock at the expected value $v_0 = \pi v_h + (1 - \pi)v_\ell$.

Now, suppose our risk-neutral agent at time 0 is asked to trade with an omniscient “informed” counterparty who knows the time 1 value of the stock. If our “uninformed” agent trades at a price $v_0 = \pi v_h + (1 - \pi)v_\ell$, he or she will always lose money: the counterparty buys the asset only if the value will be v_h at time 1, and sells the asset only if the value will be v_ℓ at time 1.

In equilibrium, of course, the uninformed trader rationally anticipates such adverse selection. Thus, if the informed counterparty wishes to buy the stock,

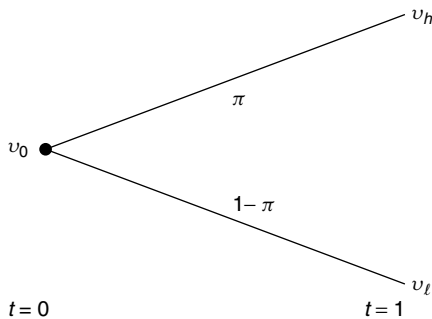

Figure 1 Single-period binomial tree

the uninformed trader is only willing to sell it at v_h . Similarly, the uninformed trader is only willing to buy the stock at v_ℓ . The possibility of adverse selection thus manifests itself as a spread between the ask price (the price at which he or she sells the stock) and the bid price (the price at which he or she buys the stock), thereby imposing a cost on all traders in the market.

The binomial example is perforce stark: we assumed that the counterparty was perfectly informed. More generally, suppose the counterparty is perfectly informed with some probability $\gamma > 0$, and uninformed with probability $1 - \gamma$. Then, we recover the essence of the Glosten and Milgrom [7] model (see **Glosten–Milgrom Models**). The bid–ask spread is easily seen to be increasing in γ .

To take the argument one step further, suppose there are a continuum of states at time 1, and the quantity an informed trader wishes to trade at time 0 is strictly increasing in value at time 1, v_1 , holding fixed the price of the asset. Then, the uninformed agent should infer that v_1 is higher when the net buy order is higher, so the bid–ask spread is naturally increasing in the quantity of shares traded. This intuition lies behind the Kyle [11] model (see **Kyle Model**).

Adverse Selection in Limit Order Markets

There is no market-maker in a limit order market; rather, traders transact directly with each other by posting orders (or price–quantity pairs) in a limit order book, and accepting the orders of other traders. The passage of time since a limit order was submitted allows for new information to arrive at the market. Thus, as Copeland and Galai [3] demonstrate, a limit order is inherently subject to adverse selection.

Suppose v_s , the expected value of the asset at time t_s , given all information available to that time, follows some stochastic process. Two kinds of agents are willing to trade in the market: liquidity or noise traders, who are uninformed, and informed traders. Liquidity traders are motivated to trade by unmodeled hedging or portfolio considerations. Each liquidity buyer i has a reservation value v_i^b , which comes from some distribution F , and is willing to buy at any price less than v_i^b . Informed traders, on the other hand, will buy only at a price less than v_s and sell only at a price above v_s . Each arriving trader is a liquidity trader with probability q_ℓ and an informed trader with probability $1 - q_\ell$.

Now, consider an agent who places a sell order at time t_0 , at an ask price $p_0 > v_0$. Suppose a new trader arrives in the market at time $t_1 > t_0$. There are two possibilities: (i) The buyer is an uninformed trader. Then, with probability $1 - F(p_0)$, no trade occurs. A transaction occurs with probability $F(p_0)$, with the limit order seller earning a payoff $p_0 - E(v_1 | v_0)$. (ii) The buyer is an informed trader. Then, with probability $\Pr(v_1 < p_0)$, no trade occurs. With probability $\Pr(v_1 \geq p_0)$, a transaction occurs, and the payoff to the limit order seller is $p_0 - E(v_1 | v_0, v_1 > p_0) < 0$.

Adverse selection results in the overall transaction probability, $q_\ell F(p_0) + (1 - q_\ell) \Pr(v_1 \geq p_0)$, being higher when $v_1 > p_0$. As Glosten [5] points out, the knowledge that the seller traded with an informed buyer raises the expected value of the asset from $E(v_1 | v_0)$ to the upper tail expectation $E(v_1 | v_0, v_1 > p_0)$.

The price at which the sell limit order is posted, p_0 , is chosen to maximize the submitter's overall expected payoff. Thus, even a relatively simple model of limit orders with asymmetric information involves a complicated decision on the part of a limit order submitter.

Informed Traders Submitting Limit Orders

To take this one step further, an informed trader may submit a limit order. Then, we have double-sided adverse selection: both the trader at t_0 and the trader at t_1 may find themselves trading with a counterparty who possesses better information about the asset's value.

In equilibrium in such a model, will an informed trader submit limit or market orders? This question is posed by Goettler *et al.* [8]. In their infinite horizon model, a Poisson process determines trader arrival. An uninformed trader observes v with a lag Δ . Traders may reenter the market with some delay. Let $\omega_s = \{L_s, (\hat{x}_s, \hat{p}_s), v_{s-\Delta}, v_s\}$ denote the state at time t_s ; the state includes the current limit order book L_s , whether the most recent transaction resulted from a market buy ($\hat{x}_s = 1$) or sell ($\hat{x}_s = -1$) order, the price $\hat{p}_s$ at which the most recent transaction occurred, and the lagged ($v_{s-\Delta}$) and current (v_s) expectations of asset value. An informed trader observes the state at the time he or she enters the market. An uninformed trader observes a subset of the state, $\{L_s, (\hat{x}_s, \hat{p}_s), v_{s-\Delta}\}$. A trader i who executes an order

(x, p) when the asset value is v obtains a payoff $x(\alpha_i + v - p)$, where $x = \pm 1$ denotes the direction of the order, p the price at which it is submitted, and α_i is a private benefit to trade (in the absence of such a private benefit, a no-trade theorem applies, and no transactions occur). A limit order changes the book to L'_s , thus affecting the states viewed by future traders.

Let $\phi(v, \tau | \omega, x, p)$ be the probability that a trader executes at time $t_{s+\tau}$ when the value of the asset is v , if he or she takes action (x, p) in state ω . For an informed trader, adverse selection is manifested in the $\phi(\cdot)$ function, which, in equilibrium, is increasing in v for sell orders and decreasing in v for buy orders. In other words, sell orders are more likely to execute when the asset value has increased (so the sell price is too low) and buy orders when the asset value has decreased (so the buy price is too high). An uninformed trader must take a further expectation over the true state ω and thus faces an added layer of adverse selection.

The model is solved numerically. Given the parameters chosen, in equilibrium, over 50% of the time, informed traders have limit orders at the best quotes, the exact proportion varying with asset characteristics. As a result, both the bid and ask prices and order depths from the limit order book are informative about the value of the asset. Uninformed traders therefore update their beliefs about value on observing the book, which mitigates adverse selection.

Thus, in a limit order market, we can expect both limit order submitters and market order submitters in a limit order market to face adverse selection. This result is consistent with the earlier analytic work of Chakravarty and Holden [2], who predict that an informed trader will use both market and limit orders. Bloomfield *et al.* [1] find that informed traders do use both market and limit orders in an experimental asset market.

Empirical Evidence

Quantitative estimates of the adverse selection component of the bid-ask spread vary by sample. Glosten and Harris [6] propose using the direction of trade to estimate the adverse selection component of the bid-ask spread in a quote-driven market. Their basic

regression equation may be written as

$$\Delta P_t = c_0(Q_t - Q_{t-1}) + \alpha Q_t V_t + \epsilon_t \quad (1)$$

where ΔP_t is the change in transaction price from $t-1$ to t , Q_t is a trade direction indicator (+1 for a market buy and -1 for a market sell), V_t is the size of the order, and ϵ_t is the change in price due to public information. Here, $c_0 + \alpha$ equals the half-spread, with c_0 representing the transitory component due to market-maker costs of supplying liquidity and α the permanent component due to adverse selection. On a sample of 250 NYSE stocks over a 14-month period from December 1981 to January 1983, they estimate that the adverse selection component is on average about 18% of the bid-ask spread.

Madhavan *et al.* [12] extend the basic model to allow for $E[Q_t | Q_{t-1} = 1] = \rho$, the first-order autocorrelation in order flow. The adverse selection component depends on the innovation in order flow. They use generalized method of moments to estimate the model on 274 NYSE stocks over the year 1990, and find that the spread and the adverse selection component both vary by time of day, being largest in the initial half-hour of trading. Estimates of the adverse selection component vary from 51% of the spread in the first half-hour to 35–36% over the latter half of the day. Gibson *et al.* [4] conduct a spread decomposition in the postdecimalization era, and find that although overall spreads are lower, the proportion due to adverse selection and inventory holding costs has increased to 55–59% of the total spread.

A different approach to determining the effect of information on prices is taken by Hasbrouck [9], who specifies a vector autoregression for trade direction and the midpoint of the bid and ask quotes. The permanent price impact of an innovation in the trade process then reflects the effect of information in the market. He finds that the full price impact occurs with a protracted lag, suggesting that information is revealed slowly in the market.

Empirical work on adverse selection in limit order markets is based on Glosten's [5] model of an electronic limit order book. de Jong *et al.* [10] find that adverse selection accounts for 25% (small orders) to 60% (large orders) of the spread on the Paris Bourse over a 44-day period in 1991. Sandås [13] conducts a structural test of the model's restriction that bid prices be equal to the lower tail

expectation of asset value given the order size, and ask prices be equal to the corresponding upper tail expectation. The model is rejected, with the slope of the limit order book being too steep. This finding, interestingly, is consistent with noncompetitive limit order submission, suggesting that informed traders submit some proportion of limit orders.

Conclusion

Adverse selection is important to asset pricing for two reasons. First, in a frictionless market, the bid-ask spread should be zero, with all trades occurring at the price v_0 . However, because of the potential asymmetric information between traders, there is now a cost associated with changing a position in the asset. Indeed, if the adverse selection problem is sufficiently severe, the market may even close down.

Second, adverse selection represents a dimension of counterparty risk that is unhedgeable: one cannot directly trade on the event that the counterparty is informed, since such information is typically unverifiable in a court. Thus, we cannot create a replicating portfolio to hedge this risk, so that asymmetric information across traders implies that markets are fundamentally incomplete. This incompleteness may directly affect traders' valuation for an asset and therefore the risk-neutral probabilities themselves.

Price Impact

Price impact refers to the correlation between an incoming order (to buy or to sell) and the subsequent price change. That a buy trade should push the price up seems at first sight obvious and is easily demonstrated empirically, as we will review below. It is also a dour reality for traders for whom price impact is tantamount to a cost: their second buy trade is on average more expensive than the first because of their own impact (and *vice versa* for sells). Monitoring and controlling impact is therefore one of the most active and rapidly expanding domains of research within trading firms. The most important questions are related to the volume dependence of impact (do larger trades impact prices more?), and the temporal behavior of impact (is the impact of a trade immediate and permanent, or is there some lag dependence of the impact?).

A moment of reflection suggests that the interpretation of price impact is far from trivial, and may even lead to contradictions—isn't a transaction a fair deal between a buyer and a seller? So why is there price impact? Three distinct possibilities come to mind:

1. *Agents successfully forecast short term price movements and trade accordingly.* This can result in measurable correlation between trades and price changes, even if the trades by themselves have absolutely no effect on prices at all. If an agent correctly forecasts price movements and if the price is about to rise, the agent is likely to buy in anticipation of it. But in this framework “noise induced” trades, based on no information at all, should have no price impact.
2. *The impact of trades reveal some private information.* The arrival of new private information causes trades, which cause other agents to update their valuations, leading to a price change. But if trades are anonymous and there is no easy way to distinguish informed traders from noninformed traders, then all trades will impact the price since other agents will believe that a fraction of these trades might contain some private information.
3. *Impact is a statistical effect due to order flow fluctuations.* Imagine, for example, a completely random order flow process that leads to a certain order book dynamics (see, e.g., [7] for a description of such models). Conditional to an extra buy

order, the price will on average move up if everything else is kept constant. Fluctuations in supply and demand can thus be completely random, unrelated to information, and still a well-defined notion of price impact will emerge. In this case, impact is a completely mechanical—or better, statistical—phenomenon.

All three of these mechanisms result in some “price impact”, that is, a positive correlation of trading volume and price movement, but they are conceptually very different. In the first two pictures, as emphasized in [13], “orders do not *impact* prices.” It is more accurate to say that orders *forecast* prices.” In the second picture, price impact is of paramount importance to understand how information gets incorporated into prices. If some traders really have an information on the “true” price at some time in the future, then the observation of an excess of buy trades allows the market to guess that the price will move up and to change the quotes accordingly (*see Glosten–Milgrom Models; Kyle Model*; for explicit implementations). Thus, while on one hand market impact is a friction, it should also be viewed as the mechanism that allows prices to adjust to new information.

But if the third, mechanical, interpretation is correct, correlation between price changes and order flow is a tautology. If prices move only because of trades, “information revelation” may merely be a self-fulfilling prophecy that would occur even if the fraction of informed traders is zero. Possible differences between these pictures may come about in the volume dependence and temporal behavior of impact, which we discuss below.

Linear and Permanent Impact: The Kyle Model

The simplest assumption is that impact is both linear in the traded volume and permanent in time. These assumptions can be partly justified within the Kyle model [17], where an insider trader and noise traders submit orders that are cleared by a market maker (MM) every time step Δt . In this model, the price adjustment rule Δp of the MM must be linear in the total signed volume ϵv , that is,^a

$$\Delta p = \lambda \epsilon v \quad (1)$$

where λ is a measure of impact, and is inversely proportional to the liquidity of the market. This price

adjustment is furthermore *permanent*, that is, the price change between time $t = 0$ and $t = T = N \Delta t$ is

$$p_T = p_0 + \sum_{n=0}^{N-1} \Delta p_n = p_0 + \lambda \sum_{n=0}^{N-1} \epsilon_n v_n \quad (2)$$

This formula assumes that the impact $\lambda \epsilon_n v_n$ of trades in the n th time interval persists unabated up to time T . Huberman and Stanzl [15] and Farmer [6] show that the linear price adjustment of the Kyle model is the only specification that does not allow price manipulations, *provided impact is permanent* (see below). From the above equation, it is clear that the sign of the trades must be serially uncorrelated if the price is to follow an unpredictable random walk. Within the setting of the Kyle model, the trading schedule of the insider is precisely such that the ϵ_n are uncorrelated [17]. But data from real markets reveal correlations of the sign of the traded volume over long timescales; we will come back to this important point below.

Measures of Price Impact

An interesting measure of price impact is the correlation between the price change between 0 and T and the sign of the trade at time 0, defined, in general, as

$$R(T) = E[(p_T - p_0) \cdot \epsilon_0] - E[(p_T - p_0)] E[\epsilon_0] \quad (3)$$

In the following, we will assume that drifts can be neglected so that only the first term in the right-hand side (RHS) is not zero. This is often the case, in practice, if T is chosen to be sufficiently small and/or if there is no strong buy/sell asymmetry ($E[\epsilon_0] = 0$).

Within the Kyle framework where the ϵ 's are uncorrelated, $R(T)$ is easily computed and is found to be

$$R(T) = \lambda E[v] \quad (4)$$

The impact function $R(T)$ is therefore *lag independent* in this model. One can, of course, also define a volume-dependent impact function by conditioning the above average on the incoming volume, that is,

$$R(T, v) = E[(p_T - p_0) \cdot \epsilon_0 | v_0 = v] \quad (5)$$

which, in the Kyle model, is equal to λv , for all T . Note that both $R(T)$ and $R(T, v)$ *a priori* depend

on the choice of the elementary timescale Δt , but we want to avoid heavy notations and skip this extra variable dependence.

Another commonly used measure of impact is the correlation $\rho(T)$ between the price change from 0 to T and the total signed volume in the same interval, or, more precisely,

$$\rho(T) = \frac{E\left[(p_T - p_0) \cdot \sum_{n=0}^{N-1} \epsilon_n v_n\right]}{\sqrt{E[(p_T - p_0)]^2 E\left[\left(\sum_{n=0}^{N-1} \epsilon_n v_n\right)^2\right]}} \quad (6)$$

In the Kyle model, this correlation is trivially equal to unity, but this correlation can decrease if liquidity fluctuates (λ becomes time dependent), or if other sources of volatility are taken into account. For example, the MM can revise his quotes in the absence of any trades, say, because of some incoming news. This can be modeled by adding an extra term in equation (2) above.

$$p_T = p_0 + \lambda \sum_{n=0}^{N-1} \epsilon_n v_n + \sum_{n=0}^{N-1} \eta_n \quad (7)$$

where the η_n 's are uncorrelated increments, representing causes of price variations not directly related to trading.

It is often useful to generalize the above definition of $\rho(T)$ by replacing the volumes v_n by v_n^ψ , where ψ is a certain exponent. As discussed below, the measured correlations are found to be stronger when $\psi < 1$.

Empirical Facts

Here we summarize briefly the salient empirical facts that emerged in the last 20 years, concerning the volume dependence and the temporal behavior of impact (see [3] for a recent review). Note that to characterize impact empirically, one has to specify two timescales: (i) the “elementary” timescale Δt over which trades are aggregated; (ii) the timescale T over which the impact of the initial trade is measured.

Concave Volume Dependence

The Kyle model assumes linear dependence of impact on the traded volume. One can measure

the volume-dependent *instantaneous* impact function $R(T = \Delta t, v)$ for different elementary timescales Δt , ranging from the average transaction time to several hours or days. One typically finds that the volume dependence of this impact is *sublinear* and well described by a power-law:

$$R(T = \Delta t, v) \propto v^{\psi(\Delta t)}; \quad \psi(\Delta t) \leq 1 \quad (8)$$

The exponent ψ increases with the elementary timescale, taking rather small values $\psi \simeq 0.1 \rightarrow 0.3$ for individual trades, and increasing toward $\psi = 1$ when Δt corresponds to several thousands of trades, with some concavity remaining for large volumes [14, 20]. The correlation coefficient $\rho(T = \Delta t)$ similarly increases as Δt increases, and reaches rather large values > 0.5 for daily returns of individual stocks, futures, or currencies [5].

Note that the small value of ψ at the individual trade level means that impact is only weakly dependent on volume, in line with many studies that show a stronger correlation of price changes with the *number of trades* rather than with the traded volume [16]. The small value of ψ is often interpreted in terms of discretionary trading: large market orders are only submitted when there is a large prevailing volume at the best quote, a conditioning that mitigates the impact of these large orders.

The above results are established using the total aggregated signed volumes, independent of the origin of the trades. Large brokerage or trading firms can also measure the price impact of their own trades; a concave impact function is usually observed with a value of ψ close to $1/2$ [1] (*see Execution Costs*). For example, the BARRA price impact model posits that, on a time interval Δt needed to complete a typical trade,

$$R(\Delta t, v) = A\sigma\sqrt{\frac{v}{V}} \quad (9)$$

where σ is the volatility per unit time and V the traded volume per unit time, and A a numerical coefficient of order unity [2]. Different theoretical justifications for this square-root impact law are given in [2, 11] and [8].

In the case of stocks, one can also study empirically the influence of the market capitalization M . One finds that when Δt corresponds to a single trade, the data can be approximately rescaled as [18]

$$R(\Delta t, v) \approx M^{-0.3} F\left(M^{0.3} \frac{v}{V}\right) \quad (10)$$

where $\bar{v}$ is the average volume per trade for a given stock, and $F(\cdot)$ a master function that behaves as a power law with exponent ψ .

Impact Cannot be Permanent

As we observed above, a permanent impact model leads to unpredictable price changes only if the signed volume is uncorrelated. However, empirical data show that on a large variety of markets the autocorrelation of the signs ϵ_n decays extremely slowly with time, over at least several days, representing thousands of trades or more [3]. The order flow is therefore found to be strongly persistent and predictable. This comes from the fact that even “highly liquid” markets only offer very small volumes for immediate execution. The fact that the outstanding liquidity is so small has an immediate consequence: trades must be fragmented, and need several hours, days, or even weeks to be completed. This clearly creates long memory in the sign of the order flow and shows that private information can only be *slowly* incorporated into prices. This observation, however, is incompatible with a permanent impact model such as equation (2), which would lead to trends, that is, strongly autocorrelated price changes.

Nonlinear Transient Impact

To reconcile persistent order flow with nearly unpredictable price changes, one can postulate a nonlinear, transient impact model that generalizes equation (2) above.

$$p_T = p_{-\infty} + \lambda \sum_{n=-\infty}^{N-1} G(N-n) \epsilon_n v_n^{\psi} \quad (11)$$

where $G(\ell)$ describes the temporal behavior of impact. One can show that it is possible to choose a certain *decaying shape* for the impact function $G(\ell)$ such as to offset exactly the autocorrelation of the order flow and ensure that the price changes are white noise.

Assume for simplicity that volumes are all equal: $v_n \equiv v, \forall n$. One can then show that if $C(\ell) = E[\epsilon_n \cdot \epsilon_{n+\ell}]$ decays for large ℓ as $\ell^{-\gamma}$ with $\gamma < 1$ (typically $\gamma \approx 0.5$ for stocks), then $G(\ell)$ should itself decay to zero as $\ell^{-\beta}$ with $\beta = (1 - \gamma)/2$ [4]. A permanent impact component $G(\ell \rightarrow \infty) > 0$ is only compatible with the random nature of prices if $C(\ell)$

decays fast enough ($\gamma > 1$). Within this transient impact model with fixed volume of trades, the relation between the price impact function $R(T)$, $G(\ell)$, and $C(\ell)$ reads [4] as follows:

$$\begin{aligned} R(T = \ell \Delta t) &= \lambda v^\psi \left[G(\ell) + \sum_{0 < j < \ell} G(\ell - j) C(j) \right. \\ &\quad \left. + \sum_{j > 0} [G_0(\ell + j) - G_0(j)] C(j) \right] \end{aligned} \quad (12)$$

In other words, the impact $G(\ell)$ of a single trade in isolation is different from the directly measurable impact $R(T)$, which picks up contributions from the fact that trades tend to repeat themselves in the same direction.

Note that even if the impact $G(\ell)$ of an individual trade decays with time, one can show that both the total impact $R(T)$ and the correlation $\rho(T)$ defined by equation (6) tend to a nonzero limit when T is large, whenever the relation $\beta = (1 - \gamma)/2$ holds.

Finally, we mentioned above that the linear impact model, corresponding to $\psi = 1$, is the only choice consistent with the absence of price manipulation strategies if impact is permanent ($\beta = 0$). But if impact is transient, other values of $\psi \leq 1$ become acceptable. Gatheral has recently shown that if $\beta + \psi \geq 1$, price manipulation is not possible [9].

Surprise in the Order Flow

If one insists *a priori* that prices must follow a strict random walk, then only the *surprise* in the order flow can impact the price. In other words, the impact of the trades in the n th interval of time Δt should read (neglecting volume fluctuations) as follows:

$$\Delta p_n = \lambda v^\psi (\epsilon_n - E[\epsilon_n | I_{n-1}]) \quad (13)$$

where I_{n-1} is the information set available just before the n th interval of time. If the ϵ_n 's are independent, then $E[\epsilon_n | I_{n-1}] = 0$ and one recovers the specification of the Kyle model. If, on the other hand, the ϵ_n 's are correlated, then one can form a prediction for the next value of ϵ_n based on the past realizations $\epsilon_{m < n}$, such that the surprise component $\epsilon_n - E[\epsilon_n | I_{n-1}]$ is, by construction, uncorrelated for different times. Within this simplified framework,

there are only two possible outcomes: either the sign of the n th transaction matches the sign of the predictor $E[\epsilon_n | I_{n-1}]$, or the signs are opposite. It is easy to show that the more likely outcome, that is, $\epsilon_n = \text{sign}(E[\epsilon_n | I_{n-1}])$, has the smaller impact [10]. Because of the positive correlation in order flow, the impact of a buy following a buy should be less than the impact of a sell following a buy—otherwise trends would appear. The detailed microstructural mechanism for such an history-dependent asymmetric impact is a topic of research (see [3] and references therein).

Using a linear autoregression model for $E[\epsilon_n | I_{n-1}]$ allows one to identify the above surprise model, equation (13), with the transient impact model of the previous section. Following Hasbrouck's VAR model [12], one may assume that

$$E[\epsilon_n | I_{n-1}] = \sum_{j=1}^{\infty} a_j \epsilon_{n-j} \quad (14)$$

where the coefficients a_j can be computed from the sign autocorrelation $C(\ell)$ using standard methods in filtering theory. Then the above transient impact model is precisely recovered provided the following identification holds:

$$G(\ell) = 1 - \sum_{j=1}^{\ell-1} a_j \quad (15)$$

Spread and Impact are Two Sides of the Same Coin

Since MMs (or liquidity providers) cannot guess the surprise of the next trade, they post a bid price b_n and an ask price a_n given by

$$\begin{aligned} a_n &= p_{n-1} + \lambda v^\psi (1 - E[\epsilon_n | I_{n-1}]); \\ b_n &= p_{n-1} + \lambda v^\psi (-1 - E[\epsilon_n | I_{n-1}]) \end{aligned} \quad (16)$$

The above rule ensures no *ex post* regrets for the market maker: whatever the sign of the trade, the traded price is always the “right” one [19]. The bid-ask spread S is then given by:

$$S = a_n - b_n = 2\lambda v^\psi \quad (17)$$

showing that spread and impact are two sides of the same coin: liquidity providers must be compensated for the adverse impact of market order trades (*see Adverse Selection; Limit Order Markets*). Conversely, one sees that the impact of trades is expected to be proportional to the bid–ask spread, suggesting that the volatility per trade σ_1 is also proportional to the bid–ask spread. Such a correlation is well supported by empirical data [21]. The relation with the volatility *per unit time* σ involves the trading frequency f , through $\sigma = \sigma_1 \sqrt{f}$.

Conclusion

Although “price impact” seems to convey the idea of a forceful and intuitive mechanism, the story behind it might not be that simple. Empirical studies show that the correlation between signed order flow and price changes is indeed strong, but the impact of trades is neither linear in volume nor permanent, as assumed in several models, such as the Kyle model. Impact is rather found to be strongly concave in volume and transient, the latter property being a necessary consequence of the long-memory nature of the order flow. Only after averaging on a long timescale (on the order of days) may an *effective* linear and permanent model make sense. This is an important observation not only for monitoring and control of execution costs but also for building agent-based models of market activity that often posit linear and permanent impact. Coming back to Hasbrouck’s [13] comment –do trades *impact* prices or do they *forecast* future price changes? Since trading on modern electronic markets is anonymous, there cannot be any obvious difference between “informed” trades and “uninformed” trades if the strategies used for their execution are similar. Hence, the impact of any trade must statistically be the same, whether informed or not informed. Impact indeed allows private information to be reflected in prices, but by the same token, random fluctuations in order flow (induced by noise traders) must also contribute to the volatility of markets.

End Notes

^a $\epsilon = +1$ if the volume of buys v_b is larger than the volume of sells v_s in the time interval Δt , and $\epsilon = -1$ in the opposite case; and $v = |v_b - v_s|$.

Inventory Effects

Traditional economic models of price-setting focus on call-auction markets in which all trading occurs simultaneously, at preestablished discrete times, with no market makers involved. Such models leave no role for any of the three sources of friction found in modern models of market liquidity: inventory, **order-processing costs**, and **adverse selection**. As market microstructure research has developed, researchers studying the links between inventories and liquidity have shed considerable light on how market makers resolve temporal imbalances in the continuous trading environment that characterizes most financial markets.

Linking Inventories and Liquidity

The study of how inventories affect pricing and liquidity in financial markets began with the work of Garman [6]. Garman models continuous trading with a market maker, or dealer, who smooths out temporary imbalances in other traders' orders to buy and sell securities. In Garman's model there is a single risk-neutral, monopolistic dealer who faces stochastic order arrival. The dealer has no ability to borrow either cash or securities, and he sets prices at which he is willing to sell (ask price) and buy (bid price) only once, before trading begins. The dealer's objective is to maximize his expected profit per unit of time subject to avoiding bankruptcy or failure. This formulation gives rise to a classic gambler's ruin problem. By setting his ask price higher than his bid price (a positive **bid–ask spread**), the dealer protects himself from certain failure, although he still faces a positive probability of failure. A key contribution of Garman's model is the idea that a dealer's inventory affects his viability. A limitation of his model is that all prices are set before trading begins; the dealer cannot adjust his prices as his inventory changes.

Inventory Models with No Possibility of Dealer Failure

Amihud and Mendelson [1] build on Garman's intuition to study how a dealer changes his prices as his inventory changes, explicitly incorporating inventory

into the dealer's pricing problem. As in Garman's model, there is a single risk-neutral, monopolistic dealer whose objective is to maximize expected profit, but Amihud and Mendelson assume that inventory is bounded above and below by exogenous parameters, eliminating the possibility of dealer failure. This allows a tighter focus on the dealer's optimization problem. This model incorporates a semi-**Markov process** in which inventory is the state variable. The decision variables (bid and ask prices) depend on the level of the state variable (inventory)—thus the bid and ask prices change over time as the level of inventory changes. Amihud and Mendelson's model predicts that the dealer's optimal ask price is above his bid price, but in this model the positive spread reflects the dealer's market power. (Extending the model to include competitive dealers would drive the spread to zero.) In addition, Amihud and Mendelson find that the dealer has a preferred or target inventory position, and he adjusts his prices to return to his target inventory. If the dealer is too long, to reduce inventory toward his target level he lowers both the bid and ask prices to induce other traders to buy. The reverse is true if the dealer is below his target inventory: To raise inventory toward its target level the market maker raises both the bid and ask prices to induce other traders to sell. Amihud and Mendelson's model thus predicts that the level of bid and ask prices is a monotonically decreasing function of the dealer's inventory. In the special case of linear supply and demand, higher inventory leads to wider spreads.

The models of Stoll [19] and Ho and Stoll [10, 11] maintain the assumption that the dealer cannot go bankrupt, but they focus on how a risk-averse dealer's inventory, **order-processing costs**, and **adverse selection** risk affect his pricing. The dealer is willing to alter his portfolio away from his desired position to accommodate the trading desires of others. The dealer is risk averse and cannot hedge his inventory exposure, so he must be compensated for bearing the risk of changing his portfolio from his target level. In these models the spread between bid and ask prices arises as compensation for the portfolio risk borne by a risk-averse dealer. Inventory causes the dealer to move both bid and ask prices up (if he is below his target portfolio) or down (if he is above his target portfolio) by the same amount, so inventory affects the level of bid and ask prices but not the magnitude of the spread between them. But

here the spread reflects dealer risk aversion, rather than market power as in [1]. Ho and Stoll [10, 11] demonstrate that the intuition of inventory affecting a dealer's quote levels but not the magnitude of his spread is robust to multiperiod and multidealer configurations. In a multidealer setting, Ho and Stoll [11] further predict that relative inventory positions among dealers determine the amount of interdealer trading.

Inventory Models with Capital Constraints

Most of the classical inventory models [1, 10, 11, 16, 19] assume either explicitly or implicitly that dealers have access to unlimited additional capital. Recent work by Brunnermeier and Pedersen [2] and Gromb and Vayanos [7] relaxes this assumption, examining how liquidity provision is affected by the inventory of dealers or arbitrageurs who face capital constraints.

Brunnermeier and Pedersen [2] construct a model linking an asset's market liquidity with market makers' funding, explicitly acknowledging that market makers generally cannot raise new capital instantly. In this model, market makers are risk neutral and their objective is to maximize final wealth, subject to the constraint that the total margin (the amount of capital required to finance their inventory positions) cannot exceed their capital. Brunnermeier and Pedersen show that when market makers' margin requirements approach their available capital, market makers provide less liquidity to the market and bid-ask spreads widen. This model thus predicts that very large inventory positions lead to wider spreads, in contrast to the capital-unconstrained models in which inventories have no effect on the magnitude of bid-ask spreads. Further, Brunnermeier and Pedersen predict that when large inventory positions push market makers close to their capital limits, market makers provide liquidity mostly in lower-risk securities, causing a "flight to quality" in which risky securities become especially illiquid.

Similar predictions can be obtained from the Gromb and Vayanos [7] capital-constraints model, although their main predictions concern the welfare implications of capital-constrained market makers.

Empirical Evidence on Inventory Effects

Models of how market-maker inventories affect pricing and liquidity in financial markets all predict that

a market maker will set his ask price above his bid price for reasons including bankruptcy risk (Garman [6]), market power (Amihud and Mendelson [1]), and risk aversion (Stoll [19], Ho and Stoll [10, 11]). This prediction of a positive bid-ask spread is borne out by observations in virtually all financial markets.

All of the inventory models also predict that inventories affect the level of bid and ask prices, with market makers lowering prices to reduce their inventory when they hold large positions and raising prices when their inventory positions are low or negative. Lyons [12] and Cao *et al.* [3] find evidence of such inventory-induced quote shading in the foreign exchange market, as do Garleanu *et al.* [5] in the S&P500 index options market. However, in the futures market, Manaster and Mann [15] find that futures market makers (who differ somewhat from the typical dealer in inventory models) actually raise their prices when they have larger inventory positions, in contradiction of the inventory models' prediction. Using London Stock Exchange (LSE) data, Hansch *et al.* [8], Reiss and Werner [18], and Naik and Yadav [17] find support for market makers' controlling risk by mean-reverting their inventory positions toward a target level. Hasbrouck and Sofianos [9] and Madhavan and Sofianos [14] find evidence that specialists on the New York Stock Exchange (NYSE) have preferred inventory positions and that their inventories affect prices, but Madhavan and Smidt [13] also find that specialist inventories deviate from their target levels for periods as long as several weeks.

Several researchers analyze the link between inventories and liquidity suggested by inventory models. Consistent with the predictions of Ho and Stoll [11] for a market with competitive dealers, Hansch *et al.* [8] and Reiss and Werner [18] find that differences in inventories across dealers on the LSE affect the extent of interdealer trading, but that individual dealer inventories do not affect the magnitude of each dealer's quoted spread intraday. On an interday level, Comerton-Forde *et al.* [4] find that large NYSE specialist inventories lead to wider spreads, consistent with the predictions of capital-constraints models such as those of Brunnermeier and Pedersen [2]. Comerton-Forde *et al.* [4] also find evidence that when NYSE specialist inventories are particularly high, spreads widen more for high-risk than for low-risk stocks, supporting Brunnermeier and Pedersen's [2] inventory explanation for flight to quality.

Summary

Dealer inventory was among the first market frictions studied by market microstructure theorists. Inventory models predict that dealers set ask prices above bid prices, that they lower their quotes when they have very large inventory positions, and that they may or may not change the magnitude of their quoted spreads as their inventory changes, depending on the particular modeling assumptions. Multidealer inventory models further predict that relative inventory positions give rise to interdealer trading and determine which dealers have the best (lowest ask or highest bid) quotes in a market. These predictions have been tested and largely borne out in empirical studies to date, but the difficulty of obtaining data on dealer inventories has limited researchers' ability to test the models in some of the largest dealer markets, such as the fixed income market.

Intraday Price Efficiency

The efficient price of a security represents the present value of expected future cash flows conditional on current information. Although observed prices are estimates of this quantity, deviations can and will occur. Price efficiency measures summarize the extent of these deviations. The measures presented here focus on deviations that arise and are subsequently corrected over very short horizons within the day, and they facilitate comparisons through time as well as across securities and markets. As these measures are intended to evaluate the closeness of actual prices to efficient prices, they relate to transaction costs and describe an important dimension of overall market quality.

Measures^a

Measures of intraday price efficiency, either explicitly or implicitly, define the efficient price for a security as a random walk. New information may arrive continuously, and deviations from the random-walk benchmark can be considered to be inefficiencies. These inefficiencies arise from a variety of sources including discreteness, inventory control, and other non-information-based components of the bid-ask spread. In principle, inefficiencies could also arise from irrationality among market participants (e.g., overreacting to the size of a trade).

Hasbrouck [9] uses variance decomposition methodologies to assess inefficiencies. He defines the (log) transaction price, p_t , as the sum of a random-walk component (the efficient price) m_t , and a transitory, mean-zero pricing error, s_t , where t indexes transaction time:

$$p_t = m_t + s_t \quad (1)$$

The efficient price is unobservable and its innovations are new public information as well as the information content of order flow. Because the pricing error has a mean of zero, its standard deviation, σ_s , is a measure of its magnitude. Intuitively, σ_s summarizes how closely transaction prices follow the efficient price over time and serves as an inverse measure of price efficiency.

Hasbrouck proposes a general structure for the pricing error, where s_t is related to information in

trades, non-trade-related public information, and a disturbance. To connect this model with the data, he uses a vector autoregression (VAR) system over $\{r_t, x_t\}$, where r_t is the first difference of p_t and x_t is a vector of trading variables. This model is underidentified, so additional restrictions from the variance decomposition literature must be imposed. Specifically, the restriction of [1] effectively relates s_t only to the trading information contained in x_t , and the vector moving average representation is used to estimate σ_s . Because of the restriction, the estimated pricing error is a lower bound. Factors that would cause σ_s to exceed this quantity must be uncorrelated with lagged returns as well as the set of trade variables.

There is no formal model describing the conditioning information in x_t , but it should be constructed to explain meaningful variation in the true pricing error. Hasbrouck uses a 3×1 vector of the following trade variables: (i) a trade sign indicator, (ii) signed trading volume, and (iii) the signed square root of trading volume. This structure of x_t allows for a nonlinear relationship between pricing error and the trade series. For some perspective, Hasbrouck uses a sample of NYSE stocks from 1989 to demonstrate that this specification increases the estimate for σ_s by about 40% over that from a simple univariate estimation of equation (1); the added explanatory power of the x_t strengthens the lower bound and provides a more accurate estimate of σ_s .

In addition to the structure of x_t , numerous methodological considerations arise. First, the VAR system must be truncated at some lag length beyond which serial dependencies are assumed negligible. There is no theoretical guidance for this decision, but one could determine a cutoff point *ad hoc* by inspecting VAR estimates over various lags. Second, trading information in x_t will typically require the signing of trades. A common method compares prices to midpoint quotes [15]. Third, overnight returns are considered atypical due to the time delay as well as different trading mechanisms at the opening and therefore may be neglected in the analysis.

A number of empirical studies have used some variant of Hasbrouck's methodology in recent years. Kumar *et al.* [14] find that pricing errors decline for equities upon option listings. George and Hwang [6] extend the model to allow for heteroskedasticity in s_t , and they find that the pricing errors are similar at the opening and close of trading. Hotchkiss and Ronen

[12] show that the price efficiency of bonds resembles that of the underlying stocks. Boehmer *et al.* [3] find that the price efficiency of NYSE stocks improved in 2002 when the contents of the limit order book were made available to traders off the exchange. Finally, Boehmer and Kelley [2] find that pricing errors decline with more institutional ownership and trading.

As an alternative to the variance decompositions, one may also measure intraday efficiency using the autocorrelation properties of the return series. Consider once again an efficient price that, by definition, follows a random walk. For a simple implementation, one can construct a series of price changes over fixed increments in time (say, 30 min) and estimate the autocorrelation. Since either positive or negative autocorrelation is a deviation from a random walk, a summary (inverse) efficiency measure is the absolute value of the autocorrelation.

A slightly more complex implementation involves variance ratios. $VR(n, m)$ is the ratio of an m -period variance to an n -period variance, where both variances are scaled by the number of periods. For example, $VR(5 \text{ min}, 60 \text{ min})$ is the ratio of a 60-min return variance to a 5-min return variance, scaled by 60 and 5, respectively. Under a random walk, variance ratios will equal 1, so the summary (inverse) efficiency measure is $|1 - VR(n, m)|$. A variance ratio contains more information than a single autocorrelation, as $VR(n, m)$ can be written as a linear combination of the first $n - 1$ autocorrelations (see [4], p. 49).

The use of autocorrelations or variance ratios also requires some methodological consideration. Most importantly, and in contrast to Hasbrouck's methodology, one needs to remove the bid-ask bounce described in [17]. The best way to do this is by computing returns according to bid-ask midpoints. In addition, for some securities, stale quotes may be a problem. One may mitigate stale quote issues by ignoring intervals over which no new quote was posted.

As a summary measure of price efficiency, the Hasbrouck approach is favorable for a couple of reasons. First, the variance decomposition methods differentiate between permanent and transient price changes and attribute deviations from a random walk to the latter alone. Nonzero autocorrelation, and hence variance ratios deviating from unity, can arise from either efficient or inefficient pricing. For

example, order splitting by informed traders may lead to positive autocorrelation. Second, pricing errors are measured in trade time—the model is advanced by one period after each trade—whereas autocorrelations and variance ratios are based on returns computed in clock time. Measuring efficiency in trade time has the added benefit of granting more weight to periods of active information discovery. Moreover, the trade-time measure reflects the actual behavior of market participants and includes the information conveyed by each single trade.

It is also important to recognize that neither the variance decompositions nor the autocorrelation-based measures will pick up deviations from the efficient price persisting for more than a brief portion of the trading day, not to mention weeks or months. That is, only pricing errors that are quickly corrected will be measured. This approach ignores potential deviations from fundamentals in contexts such as long-term reversals as in [5], return momentum as in [13], or weekly return reversals as in [16].

Boehmer and Kelley [2] have estimated a variety of price-efficiency measures for all NYSE stocks for each quarter from 1983 to 2004. Figure 1 tracks the cross-sectional average for σ_s normalized by σ_p from equation (1) over the 22-year period. For comparison, the cross-sectional average of the absolute value of the first-order autocorrelation for a series of 30-min quote midpoint returns is also shown. Autocorrelations and variance ratios incorporating various other intraday horizons produce a similar picture. Both plots illustrate a general decline through time, which is interpreted as an overall *increase* in price efficiency. This matches a similar trend in other transactions costs such as execution costs. More importantly, an inspection of the plots reveals that both measures increase around the market crash of 1987, but there is a substantial drop in σ_s alone around the 16th pricing in 1997 and on decimalization in 2001—events that intuitively should lead to greater efficiency. Turning to the cross section, unreported tests show that the average cross-sectional correlation between the two measures is around 0.25, and that both measures generally decrease with firm size, execution costs, price, and trading activity.

The Evolution of the Efficient Price

While this article focuses on the extent to which transaction prices resemble an efficient price, similar

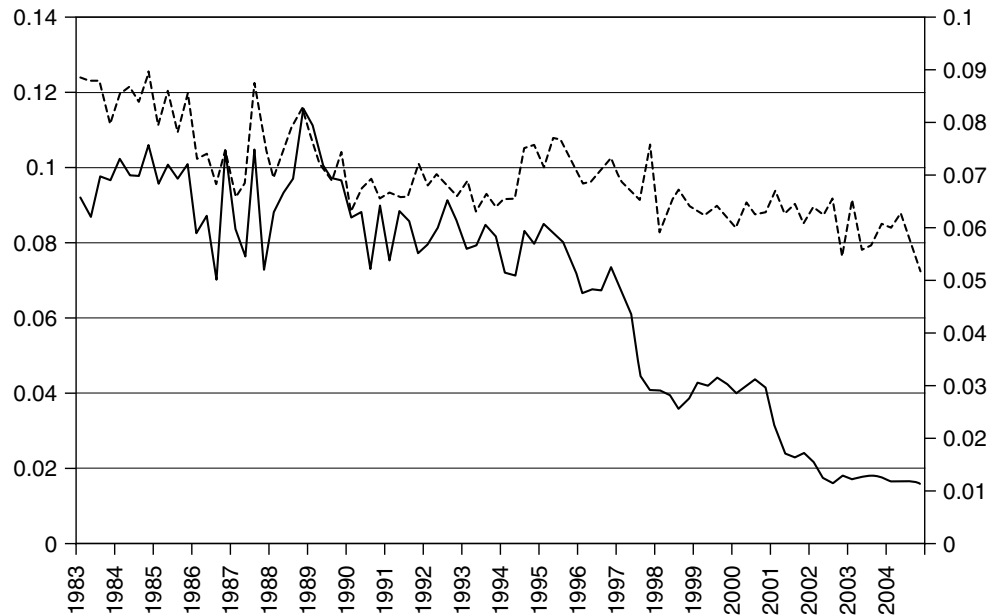

Figure 1 Average price efficiency through time. The sample is based on NYSE-listed securities between 1983 and 2004. The solid line tracks the cross-sectional mean of α_s/σ_p , which is the pricing error from Hasbrouck [9] divided by the standard deviation of transaction prices. The dashed line tracks the cross-sectional mean of $|AC30|$, which is the absolute value of the 30-min return autocorrelation. The left and right vertical axes are for α_s/σ_p and $|AC30|$, respectively

estimation techniques describe the evolution of the underlying efficient price itself.^b Specifically, Hasbrouck [7, 8] starts with equation (1) and considers a VAR over returns and trades. In this case, however, prices and returns are based on quote midpoints (rather than transaction prices) and the trade at time t precedes the quote change indexed by t . Thus, the quote change at time t reflects information in the trade, but not *vice versa*. Hasbrouck [7] uses the impulse response function as a measure of the information content of a trade innovation. He also [8] uses variance decompositions similar to the ones used by him in [9] to develop two *summary measures* of trade informativeness. The first is the component of the random-walk variance attributable to trades, which serves as an absolute measure of the private information revealed by trading. The second is the first measure scaled by the total random-walk variance. It is interpreted as the importance of trade-based information relative to all public information for price discovery. These measures are superior to other metrics such as the quoted spread or the permanent price impact (as in [7]), which condition on trade size. Finally, Hasbrouck [10] provides a multiple

market extension to assess the relative price discovery for each market in which a security trades. Here, there is a single random-walk efficient price and each market's information share is defined as the proportion of the random-walk variance attributable to its trades.

Summary

Intraday price efficiency can be measured using variance decomposition methods or by various autocorrelation-based measures. Because they explicitly characterize price changes as permanent or temporary, and they employ useful transaction-time models, variance decomposition methods are preferred. Several studies using these measures are also described.

High-frequency Data

High-frequency financial data usually refer to data sampled at a time horizon smaller than a trading day [5, 6, 8]. In this sense, high-frequency data are essentially intended as intraday data. However, the meaning of high frequency has changed over the years following the availability of more and more detailed information on the trading process. A stricter viewpoint considers those financial records where no kind of temporal aggregation is done as high-frequency data. The use of such data in finance is recent and dates to the late 1980s [16]. Among the first high-frequency databases worth mentioning are the Berkeley Option Data, containing bid–ask quotes and trade prices of option traded at the Chicago Board Option Exchange (CBOE), the TORQ database containing trades and quotes relative to 144 New York Stock Exchange (NYSE) stocks (1990–1991), the HFDF93 database of foreign exchange data released by Olsen & Associates (1992–1993), and the computerized trade reconstruction records maintained by the Commodities Futures Trading Commission (CFTC). In the following, we describe the most common types of datasets.

- **Tick-by-tick data**

The simplest form of financial data without any temporal aggregation is the so-called tick-by-tick data. In this type of data, all transactions are recorded. Typically, the dataset contains information on the time, price, and volume of each trade. Clearly, the time frequency at which data are recorded is not fixed, but can be different in different phases of a trading day (see below).

- **Trade and quote data**

A more refined type of dataset contains information on transactions and best quotes (Level 1 data). Transaction data usually contain the transaction prices, the time when the transaction occurred, and the exchanged volume. Quote data usually contain information about the best bid and the best ask price and the available volume at these prices. Quote data are usually updated every time there is a quote change either in the price or in the volume. The availability of trade and quote

data allows one to infer whether the transaction was buyer or seller initiated. The idea is to compare the trade price with the bid and ask prices of the prevailing quote, which is the most recent past quote. One of the most famous methods to assign signs to trades is by using the Lee and Ready algorithm [10]. However in some markets (e.g. NYSE), the signing process is not always straightforward because of some data and market subtleties; for a more recent discussion, see, for example, [14].

One of the most famous trade and quote database is the TAQ (Trade and Quote) database, maintained by NYSE since 1993. The trades and quotes data are available for a wide range of stock exchanges and markets worldwide.

- **Order book data**

The next level of high-frequency data resolution (Level 2 data) includes complete information about the order book in a given market. While the quote data contain information only on the best bid and best ask prices, in the order book data, all limit orders to buy or sell are recorded both when they are placed and when they expire or are canceled. This type of dataset allows one to reconstruct the limit order book at any instant of time and to follow the market dynamics more closely. A variant of this type of database contains the transaction data and the price and volume of a fixed number (usually 5 or 10) of best price levels on both sides of the order book. The use of such data dates back to the early 1990s [1]. One of the most popular databases of order book data is the Rebuild Order Book maintained by the London Stock Exchange (LSE). A different type of order book dataset provides a snapshot of the book with a fixed time frequency, rather than providing each individual event affecting the order-book dynamics. For example, the OpenBook database of the NYSE provides a snapshot of the order book refreshed every second.

- **Market member data**

Recently, a few markets have released financial datasets with another level of resolution. These datasets contain also the identity of the market members (and/or brokers, traders) involved

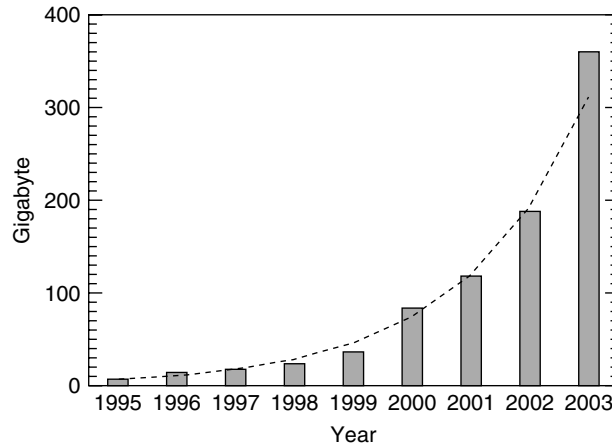

Figure 1 Size in gigabytes of the trade and quote (TAQ) database of the New York Stock Exchange during the period 1995–2003. The dashed line is a fit with an exponential function and the estimated doubling time is 1.5 years

in each transaction and sometimes of the market member who placed each limit order. For reasons of privacy, the identity of the market member is often coded, and, in some cases, the coding is different for different stocks or different time periods. This type of database allows one to identify the different strategies followed by different traders [12]. For example, the Spanish Stock Exchange releases such a database where the market member identity is completely transparent. In other markets, this information is recorded although it is not transparent to the agents during the market activity.

Two important aspects of high-frequency data are data size and time resolution. The size of high-frequency data has significantly increased in the last years because of the explosion of trading activity in financial markets. As an example, Figure 1 shows the approximate size (in gigabytes) of the TAQ database of the NYSE for the years from 1995 to 2003. The size has increased more than 50 times in magnitude, and the growth seems to be well fitted by an exponential law with a doubling time of about 1.5 years. More recently, the total volume of data related to United States large caps on a typical day of 2007 was 57 million lines, approximately a gigabyte of stored data.

The size of high-frequency data increases also when the level of data resolution is increased, for example, data on a high cap LSE stock in 2002

occupy roughly 12 kB for daily data, 15 MB for trade data, and more than 100 MB for order book data.

Concerning the issue of time resolution, very often, high-frequency data are recorded with a 1-s resolution. While this resolution was sufficient several years ago, nowadays, this resolution is insufficient to allow a correct time ordering of the market events. To give an example, at the end of 2007, Apple had on average 6 transactions per second, and on the order of 100 events per second affecting the order book. With this event frequency, it is very hard to infer the correct time ordering of events within a second. Of late, high-frequency databases are either released with a 1-ms resolution, or still have the 1-s resolution but the events are correctly sorted out within the second, according to the actual order of events.

Issues with High-frequency Data

Working with high- and ultrahigh-frequency financial data presents many additional issues when compared to the more traditional analysis of daily or weekly data. Besides the fact that high-frequency data analysis is computationally more demanding, the issues involved can be categorized into at least seven classes, which we have chosen as follows: data cleaning, irregular temporal spacing, discreteness, variable definition, daily periodicities, temporal correlations,

and market structure; we briefly review these in the following.

- **Data cleaning**

High-frequency data are often plagued by errors. Therefore it is very often necessary to perform a few preliminary steps to clean the data. A typical problem is the identification and removal of outliers. Such a cleaning procedure is quite problematic, given the arbitrariness in the definition of outliers. Typically, one considers a window of neighboring records, called the *filtering window*, and judges the plausibility of a record according to the statistical properties of the other records in the filtering window [2, 6].

- **Irregular temporal spacing**

Events such as trades, quotes, and limit order placement do not occur at regular intervals of time either in tick-by-tick data or in limit order-book data; rather they occur at irregularly spaced time intervals. In this framework, the time between events is itself a random variable with often nontrivial temporal correlations. Moreover, there are statistical dependencies between the time interval between two trades and the variables characterizing them. Figure 2 shows an example of the occurrence of irregular time spacing in a financial time series.

There are two possible approaches to the problem of irregular temporal spacing. In the first approach, one extracts a regularly spaced time series by using some kind of interpolation scheme. For example, the *previous tick interpolation* scheme uses the past most recent record as the value of the variable at a given instant of time. Alternatively, one can use a linear interpolation between the past most recent and the future most recent events to assign a value to a variable [6]. Interpolation schemes may introduce spurious correlations. The second approach makes use of models that explicitly take into account the irregular temporal spacing. Point processes [3] give a natural description of irregularly spaced events. There are several classes of models dealing with this issue, including the autoregressive conditional duration model [4] and the continuous time random walk model [13].

- **Discreteness**

When one starts dealing with events at the highest resolution level, the issue of variable discreteness cannot be neglected. For example, asset prices can only assume integer multiples of the tick size, which is the smallest allowable price change. Similarly, the volume of an order must be integer multiples of the minimum allowable number of shares in a single order. The discretization unit can also be variable in time. For example, in the last years US equities passed from a large tick

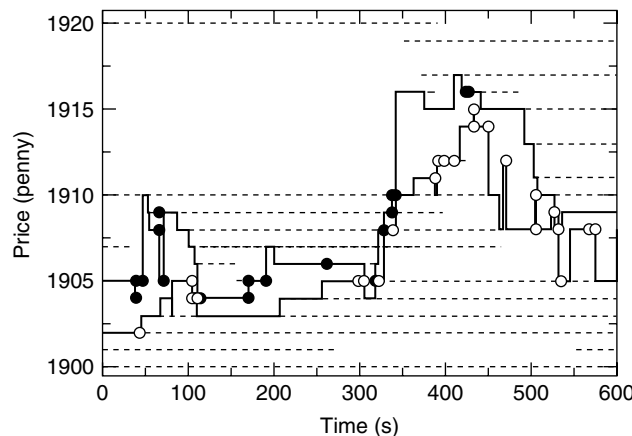

Figure 2 Graphical representation of the dynamics of the order book of the stock AstraZeneca traded at the London Stock Exchange during a 10-min interval on September 4, 2002. The filled (empty) circles are buyer- (seller-) initiated transactions. The thick lines are the bid and the ask price. The dashed lines are limit orders

size (1/8 of a dollar) to a small tick size (one cent, since 2001). The reduction of tick size has been related to several empirical facts, such as the decrease of the spreads and depths of the limit order book [7]. Many statistical models treat the variables as continuous variables, whereas from the above discussion, it is clear that at very high frequency, the variables should be treated as discrete.

- **Variable definition**

The availability of data with the resolution of quotes or of the order book raises the problem of the proper definition of variables. As an example, consider the price of an asset. At a given instant of time, there are many prices that can be considered as the relevant representative price. The most common one is the midprice, which is the mean of the best bid and the best ask prices. However, significantly different volumes may be available at the bid and at the ask, and one may wonder whether a volume-weighted average between the bid and the ask prices is a more proper definition

of price. If one wants to include not only the information on the volume at the best price but also the information of volume in part or in the entire order book, then the number of possible definitions of average price increases significantly.

- **Daily periodicity**

Financial time series at high frequency display strong daily periodicity. Among the variables having a daily periodicity, we mention volatility, trading volume, number of transactions, time between trades, and spread. The daily periodicity is due to the fact that the trading activity is not constant throughout the day. Typically, the trading activity is high around the opening, it decreases until midday, and finally increases toward the end of the trading day. This is sometimes referred to as a *U-shape pattern*. An example is shown in Figure 3. Figure 3(a)–(c) shows the mean intraday pattern for volume, volatility, and number of trades for General Electric at the NYSE. The volatility proxy is the absolute price

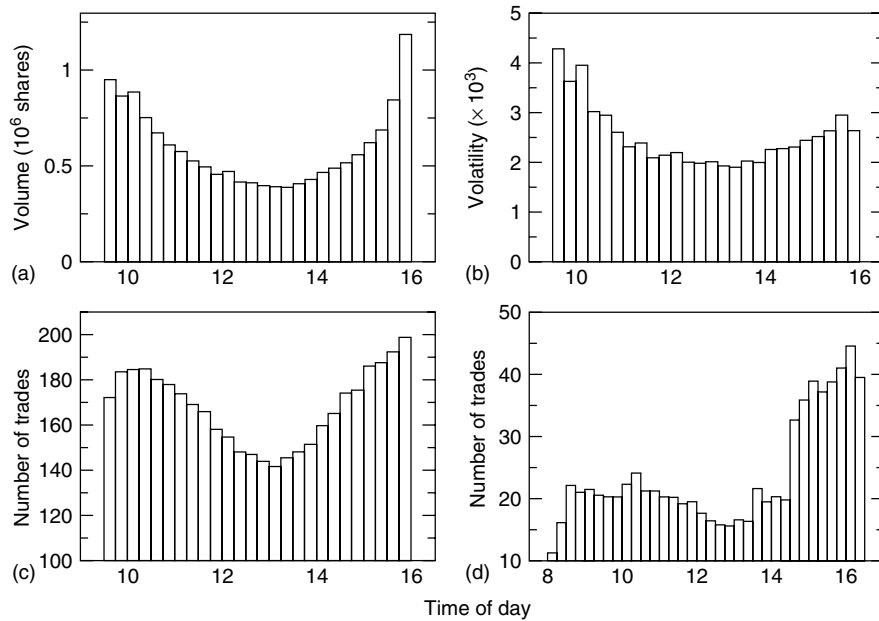

Figure 3 Examples of the intraday pattern. One bin corresponds to 15 min and the x -axis shows the hour of the day. The figure shows the traded volume (a), the absolute price change (b), and the number of trades (c) of General Electric at the NYSE during the period 2002–2003. (d) The number of trades of AstraZeneca exchanged in the electronic market (SET1) of the LSE during the period May 2000–December 2002

change here. The three quantities display a U-shape, even if the detailed shape of the U is quite different. Figure 3(d) shows the mean intraday pattern of the number of trades for AstraZeneca at the LSE. By comparing panel Figure 3(c) and (d), it is evident how the intraday pattern for a variable can be strongly dependent on the considered market. Note that in Figure 3(d) there is almost a doubling of the frequency of trades around 14:30. This is the London time corresponding to the opening of US markets. More generally, in many markets, one often observes peaks of activity or regime changes that correspond to the opening or closing of markets in other time zones.

One important consequence of daily periodicity is that financial time series are not stationary because the statistical properties of a variable depend on the time of the day. Moreover, the presence of the U-shape produces periodicities in financial time series. For these reasons, one is often interested in removing these “trivial” temporal dependencies from the series. This can be done, for example, by dividing the variable by its mean value observed in the sample at that time of the day. It is worth noting that other types of periodicity (e.g., weekly, yearly) are also present. For example, in US markets, the trading volume is larger at the middle of the week than at beginning and at the end. Usually, these periodicities are less intense than the daily periodicity.

Foreign exchange (FX) markets display different types of periodicity [6]. In fact, FX markets have no trading-hour limitations, which means that new bid–ask prices can arrive from all over the world at any time. The intraday patterns of FX variables are therefore not U-shaped. Typically, FX intraday patterns show three broad peaks that correspond to the working periods in America, Europe, and East Asia. Other seasonalities are observable in the FX data, such as the intraweek patterns that arise in connection with the fact that during the weekends the market activity is much smaller.

• Temporal correlations

Typically, financial variables sampled at high frequency display strong temporal correlations. Some temporal correlations are specific to the microstructure of financial markets at high frequency [9]. Other correlations are also present at a lower frequency but are more intense with intraday data. For example, Figure 4 shows the autocorrelation function of transaction price returns for the AstraZeneca (AZN) stock traded at LSE. The lags on the horizontal line are measured in event time. The autocorrelation function of transaction price returns is strongly negative at the first lag and then it rapidly decreases to zero. This is the well-known bid–ask bounce [15] and is mainly due to the presence of two trading

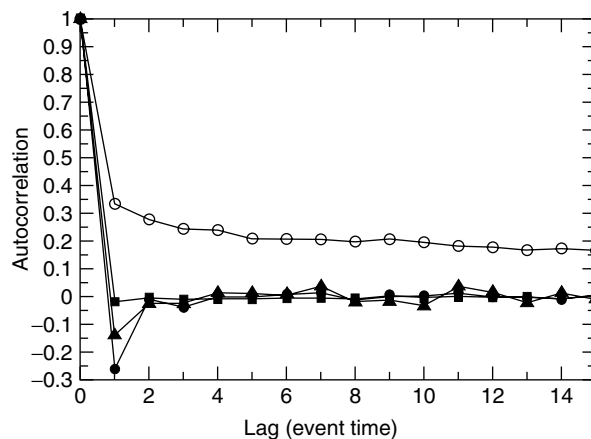

Figure 4 Autocorrelation function of transaction price returns (solid circles), absolute value of transaction price returns (open circles), returns of midprice sampled before each transaction (filled triangles), and returns of midprice sampled before each market event (filled squares) for the AstraZeneca (AZN) stock traded at LSE in 2002. The lags on the horizontal line are measured in event time

prices, one for buyer- and one for seller-initiated transactions. This negative autocorrelation disappears when one considers aggregate returns, and it is therefore a typical microstructural effect. Figure 4 shows also the autocorrelation function of the absolute value of trade price returns, considered here as a proxy of volatility. This autocorrelation function decays very slowly showing that persistency and volatility clustering can also be observed at the tick-by-tick timescale. It is important to stress that at this scale the sampling procedure plays an important role. As an example, Figure 4 shows the autocorrelation function of returns of the midprice sampled before each transaction and sampled before each market event (including limit order placements and cancellations). In the first case, a negative correlation at one lag is still present (though smaller than the one for trade price returns), whereas in the second case the negative correlation disappears. Finally, many financial variables at high frequency display strong temporal persistence that can often be modeled in terms of long memory processes. Examples include transaction rate, spread, sign of the order flow, and volume (*see Order Flow*).

• Market structure

When one works with high-frequency data, it is important to take into account the structure of the market under investigation. Many financial markets have a multiple structure composed of electronic markets, block markets, dark pools, and so on. The statistical properties of a financial variable can be quite different in different segments of the market. For example, trading volume distribution is fat tailed in the block market while it is usually thin tailed in the electronic segment [11]. Therefore, in the analysis of high-frequency data, it is important to take into account this market heterogeneity either by specializing the investigation to a given segment or by weighting the different statistical properties in a suitable way.

Order Flow

According to a common definition, “order flow is transaction volume with a sign” [1]. The sign of the volume conveys information on the initiator of the transaction. Conventionally, positive volumes are associated with buyer-initiated transactions, whereas negative volumes are associated with seller-initiated transactions. Under this definition, order flow is characterized only by orders that result in an immediate transaction. A more general definition of order flow should also include orders that do not result in an immediate transaction. More precisely, most modern financial markets work through a double auction mechanism. In these markets, impatient traders submit *market orders*, which are orders to buy or sell a given quantity of shares at the best available price,^a and are therefore immediately executed (*see Order Types*). More patient traders submit *limit orders*, which are orders to buy or sell a given amount of shares at a given price or better. If there are no counterparties willing to trade at this price, the order is added to a queue called the *limit order book*. A trader can decide to remove his/her limit order from the book whenever he/she wants and this event is called a *cancellation*. The order flow is the joint process of market and limit order placements and cancellations. The price formation process results from the interaction between these events and is the focus of market microstructure theory [1–3]. Order flow is related to supply and demand and to liquidity. More precisely, when one considers the sign of the orders, “Order flow, as used in microstructure finance, is a variant of a key term in economics excess demand” [1]. Whatever the order sign, the flow of limit orders increases the liquidity of the asset, while market orders and cancellations deplete liquidity.

Statistical Properties

The order flow is a complex stochastic process that takes place in continuous time. It has three components (limit orders, market orders, and cancellations), each component being characterized by a sign, a volume, and a price. The order flow is, furthermore, strongly dependent on the state of the limit order book. There is no available stochastic model able to

fully describe the dependence structure of this process. One usually restricts to a subpart of the order flow and attempts to describe it within a suitable reduced model.

In order to simplify the presentation, this article focuses on the statistical modeling of each component separately and refers mainly to stock markets.

Market Order Flow

The unconditional probability of the sign of a market order is very close to 1/2. The probability density function of the volume of market orders is often described by a decreasing function with a power-law tail (see Figure 1). The market order flow has very interesting temporal correlation properties. Consider, for simplicity, the symbolic time series obtained in event time by replacing buy market orders with +1 and sell market orders with −1, irrespective of the volume of the order. The autocorrelation function $C(\tau)$ of these strings of bits decays very slowly to zero and its asymptotic behavior is well fitted by a power-law function

$$C(\tau) \approx \frac{1}{\tau^\alpha} \quad (1)$$

where $\alpha < 1$ (typically $\alpha \cong 0.5$) [4, 5]. A process with such a nonsummable autocorrelation is called a *long-memory process* [6]. Panel (a) of Figure 2 shows the autocorrelation function of market order signs for AstraZeneca (AZN) traded at the London Stock Exchange (LSE). It is worth noting that the persistence in the market order flow is still statistically significant after many trading hours. The volume-weighted market order flow also shows strong temporal persistency, although weakened by the volume fluctuations (see Figure 2b). The long-memory properties of market order signs have been observed in different markets and can also be observed after temporal aggregation of the order flow. It has been proposed that the long memory is due to order splitting [7].

The persistence of market order flow raises the problem of how market efficiency is maintained. A positively correlated order flow and a fixed and permanent market impact imply positively correlated return time series, in contradiction with market efficiency. To reconcile a correlated order flow with efficiency, one has either to assume a fixed but temporary

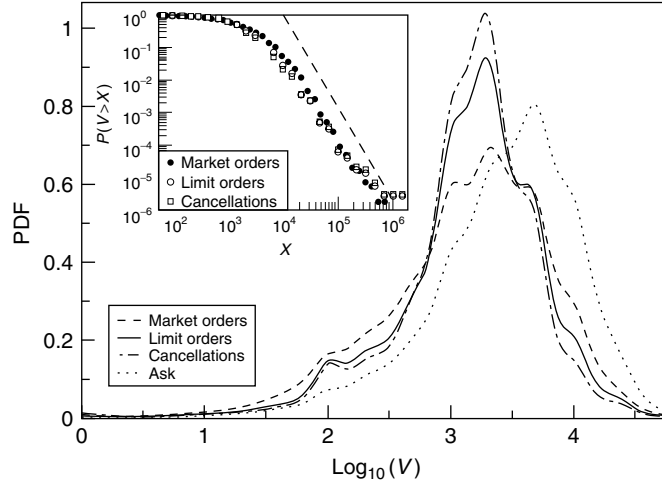

Figure 1 Probability density function of the log-volume of individual orders, for the three different components of the order flow. For comparison, the figure also shows the probability density function of decimal logarithm of the volume at the best (ask) price, sampled before each transaction. The inset shows in a double logarithmic scale the cumulative probability distribution of the volume for different types of orders. The dashed line is a power-law function with slope 2.8, which is the maximum likelihood estimator of the tail exponent for market orders. Data refer to the stock AZN traded at the LSE in the period 1999–2002

impact or a permanent but history-dependent impact [8] (*see Price Impact*).

The conditional properties of market order flow are also important. First, the size of the bid–ask spread is a key determinant of the market order flow. The rate of market orders submission, independently on their sign, decreases as the spread increases (see Figure 3). This behavior is intuitively expected since a large bid–ask spread is a strong disincentive to trade, given that the spread-related cost is large. A second conditional property concerns the volume of a market order, which is strongly dependent on the volume at the opposite best price. Specifically, it is rare that the volume of a market order exceeds the volume at the opposite best and thus that the trade penetrates more than one price level [9]. For example, in a set of 16 highly capitalized stocks traded at the LSE, approximately 86% of the market orders leading to an immediate price change have a volume exactly equal to the volume at the opposite best. Moreover, approximately 97% of the market orders leading to an immediate price change have a volume that is less than the total volume at the best and at the second-best opposite price. This indicates strong selective liquidity taking, meaning that agents condition the size of their market orders on

prevailing liquidity, making large transactions only when liquidity is high and small transactions when it is low.

Limit Order Flow

A limit order is characterized by its sign, volume, and limit price. Several statistical regularities of limit orders placement have also been observed. First, the unconditional distribution of limit order volume is similar to the one for market orders (see Figure 1). Second, the time series of limit order signs is also characterized by the long-memory property [5, 10]. Figure 2(c) shows the autocorrelation function of limit order signs for AZN. Third, several statistical regularities of limit order flow are observed when one also considers the limit price. The limit price characterizes the aggressiveness of the limit order and the patience of the trader since the probability that the order is executed in a given time interval depends on where it is placed. Limit orders in the spread are very aggressive and more likely to be executed, while limit orders placed in the book very far from the best price are less aggressive and their execution probability is low. For high cap stocks at LSE between 1999 and 2002, roughly one-third of

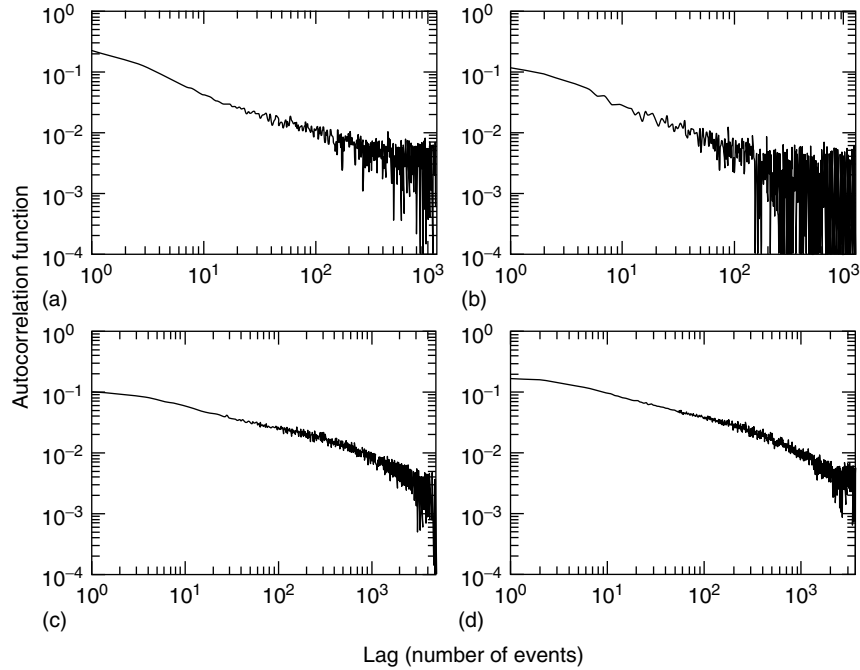

Figure 2 Autocorrelation of the order flow in event time plotted on a double logarithmic scale. Specifically, the panels show the autocorrelation function of market order sign (a), market order signed volume (b), limit order sign (c), and limit order signed volume (d). The span of the x -axis corresponds on average to two trading days. The data refer to the stock AZN traded at the LSE in the period 1999–2002

limit orders were placed inside the spread, another third at the best prices, and the last third inside the book. One of the statistical regularities recently observed is the power-law distribution of limit order price in continuous double-auction financial markets. Let $b(t) - \Delta$ denote the price of a new buy limit order and $a(t) + \Delta$ the price of a new sell limit order. Here $a(t)$ is the best ask price and $b(t)$ is the best bid price when the limit order is placed. The probability density function $\rho(\Delta)$ of the relative price Δ is very similar for buy and sell orders. Moreover, for large values of Δ , the probability density function is well fitted by a power-law function

$$\rho(\Delta) \approx \frac{1}{\Delta^{1+\mu}} \quad (2)$$

where $\mu \approx 1.5$ for LSE stocks [11], and $\mu \approx 0.6$ for stocks traded at the Paris Stock Exchange [12]. This power law extends from 1 tick to over 100 ticks (sometimes even 1000 ticks), corresponding to a relative change of price of 5 to 50%. Such a broad distribution of limit order prices tells us that the

opinion of market participants about the price of the stock in a near future could be anything from its present value to 50% above or below this value. Mike and Farmer [13] fit the distribution of relative limit prices Δ for LSE stocks with a Student distribution with 1.3 degrees of freedom corresponding to a value $\mu = 1.3$. Interestingly, the Student distribution fits relative limit order price both outside ($\Delta > 0$) and inside ($\Delta < 0$) the spread.

The rate of limit order placement strongly depends on spread. When the spread is large, the rate of limit order placement is also large (see Figure 3). This is true also if one considers only limit orders placed inside the spread (see Figure 3). The reason is that a large spread is an incentive to provide liquidity and to acquire price priority by placing a limit order in the spread. The limit order flow is also dependent on book thickness. Patient traders become more aggressive in their limit order submission when the own side book is thicker and when the opposite side book is thinner [14].

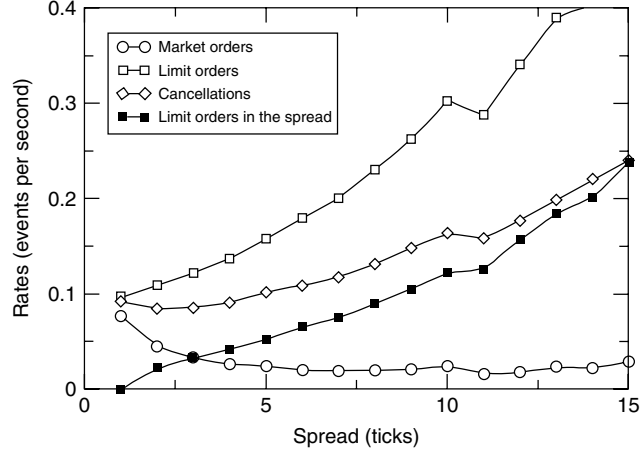

Figure 3 Rates of different types of events in the limit order book conditional to the size of the spread. The data refer to the stock AZN traded at the LSE in 2002 [Adapted from [20].]

Cancellation Flow

A limit order can be canceled or can expire and both events lead to a depletion of liquidity. Not surprisingly, the volume of canceled limit orders is distributed in a similar way to the volume of limit orders (see Figure 1). The time series of cancellation signs also displays the long-memory property (see Figure 2d). Moreover, the rate of cancellations increases with spread size (see Figure 3). This is probably due to the high limit order placement/cancellation activity observed when a temporary liquidity crisis triggers a competition between liquidity providers in order to find a new equilibrium value for the bid and ask prices. Finally, the lifetime of a given limit order (which is inversely related to the cancellation probability) increases as one moves away from the bid–ask spread [15]. This phenomenon can be explained by considering that far away orders are typically put in the market by patient investors that want to benefit from significant price swings in the medium term, while orders close to the bid and ask prices correspond to very active market participants that readjust their orders at a very high frequency. The cancellation probability at time t depends also on the ratio between the distance Δ of the limit price from the best at time t and at the time $t_0 < t$ when the order was placed. Mike and Farmer fit the cancellation probability with the functional form

$$p(t) \propto 1 - \exp[-\Delta(t)/\Delta(t_0)] \quad (3)$$

meaning that if the price moves in a direction opposite to the limit order, its cancellation probability increases [13].

Diagonal Effect

As discussed above, a common phenomenon observed in the statistics of order flow is a strong serial correlation of each component of the order flow. This phenomenon has been termed *diagonal effect* [16]. More precisely, the probability that a given type of event occurs is larger after that event has just occurred than it would be for the unconditional occurrence of the event [16]. This type of serial persistence is observed also for longer lags and it has been observed in different markets including foreign exchange markets [17]. The possible origins of these serial correlations are (i) strategic order splitting in order to reduce market impact; (ii) imitation behavior across traders that observe other participants and imitate their behavior; and (iii) traders reacting similarly to the same event. It is, in general, difficult to separate these alternative explanations. However, by using brokerage data, it has been shown that correlation in market order flow is mainly explained by order splitting [8]. Positive serial correlation of limit order flow is also due largely to order splitting and the undercutting behavior among limit order traders. Controlling for these two effects explains up to 72% of the positive serial correlation [10].

Commonality in Order Flow and Liquidity Provision

The above discussion has focused on the statistical properties of the order flow for an individual stock. However, the order flow of different stocks simultaneously traded in the same market can display mutual dependencies. Since the order flow determines the supply and demand of liquidity of a stock, this type of dependency is also called *commonality in liquidity*. When order flow is signed according to the buy/sell side, direct and indirect measures indicate that commonality in the order flows explains a consistent part (two-thirds as described in [18]) of the commonality in returns [18, 19]. By considering order flow with orders signed according to the liquidity supply or demand, empirical analysis shows that there are significant commonalities in liquidity and that a liquidity market factor exists [18, 19].

End Notes

^aIn some markets only limit orders are allowed and a limit order crossing the spread results in an immediate transaction. Thus a crossing limit order behaves as an effective market order.

Glosten–Milgrom Models

Glosten–Milgrom models analyze transaction prices arising from quotes of competing risk-neutral dealers making a market in a single security and facing both privately informed and uninformed traders. The dealers must quote bid and offer prices at which they are willing to, respectively, buy and sell. A trader arrives and decides to buy, sell, or leave. Upon seeing the outcome of the trader’s decision, the dealers modify their quotes in preparation for the next arrival. Implementation of the model thus requires a specification of the arrival processes of informed and uninformed traders and the nature of public and private information. This specification, in turn, leads to the calculation of quotes and the time series of quotes and transaction prices.

Mathematical Structure and Results

The discussion follows the analysis in [7], and proofs can be found there. The model is designed to describe trade over a relatively small interval of time in which there is private information about the future cash flows of the security, but this private information will depreciate, either through information revealed in trade or *via* public announcements of the information. By the time all asymmetric information has been resolved, at T , the value of a share of the security will be V . Prior to T , this value is not known, but at time t , there has been a history of trade and public announcements. This information is summarized by the filtration H_t . Justified by the fact that a relatively short period of time is being analyzed, the time value of money and risk aversion can be reasonably ignored, and the value of a share of stock at time t is just its expected value conditional on time t information, $E[V|H_t]$.

During the trading period, potential traders arrive at the market one by one. An arriving trader at time t observes the bid and ask quotes B_t and A_t , respectively. If the trader is informed, with information represented by F_t , a refinement of the history H_t , then the trader is presumed to buy if $E[V|F_t]$ exceeds the ask and sell, if this expectation is below the bid. Otherwise, the trader does not trade. A trader who is uninformed is presumed to have a value M_t , which could be a function of the history H_t

as well as other features of the trader’s preferences. This private valuation should be thought of as a random variable independent of private information. The uninformed trader will buy if M_t exceeds the ask price, and sell if this idiosyncratic valuation is below the bid. Describing the arrival process by an indicator variable I_t , which is one if an arrival at time t is informed and zero if uninformed, we can describe the personal valuation of an arrival at time t by $Z_t = I_t E[V|F_t] + (1 - I_t)M_t$.

Consider the quoting problem of a market maker at time t facing a possible arrival. Should the arrival buy, the market maker will receive the ask price and give up a share of stock ultimately worth V . This will happen if Z_t exceeds the ask price. Similarly, if the arrival sells at the bid, the market maker will receive a share ultimately worth V and pay the bid price. Otherwise, there will be no transaction and no profit. Thus, the expected profit to a market maker quoting bid B and ask A , is

$$E[(A - V)\mathbf{1}\{Z_t > A\} + (V - B)\mathbf{1}\{Z_t < B\}|H_t] \quad (1)$$

Assuming that dealer competition drives the expected profit for both a buy and a sell to zero, the ask and bid quotes are the solutions, if they exist, to the two fixed-point problems:

$$\begin{aligned} A_t &= E[V|H_t, Z_t > A_t] \quad \text{and} \\ B_t &= E[V|H_t, Z_t < B_t] \end{aligned} \quad (2)$$

If solutions do not exist, the market is said to close down.

The zero-profit bid and ask prices are “no regret” prices in the sense that the market maker, after having sold to an order at the ask price will revise expectations and the revised expectation is precisely the ask price. That is, to quote the ask price the dealer must determine what the revised expectations will be in the event of a purchase.

The first result is immediate and intuitive: the ask price exceeds the expectation at the time of the quote that exceeds the bid. If a buy occurs, one possibility is that the arriving trader is informed and has a valuation higher than the ask price. It could never be the case that the arriving trader is informed and has a valuation less than the ask price and buys. This alone requires that the market increase the conditional expected value in response to a buy. This argument justifies

the term *adverse selection spread* as a description of the difference between the ask price and bid in the model (see **Adverse Selection**).

The second observation follows from the fact that transaction prices occur at the “no regret” quotes. The transaction price is a conditional expectation of the terminal value, V . A transaction at time t can be written, where H_{t+} indicates the information available following a transaction at time t :

$$\begin{aligned} P_t &= A_t \mathbf{1}\{Z_t > A_t\} + B_t \mathbf{1}\{Z_t < B_t\} \\ &= E[V|H_t, Z_t > A_t] \mathbf{1}\{Z_t > A_t\} \\ &\quad + E[V|H_t, Z_t < B_t] \mathbf{1}\{Z_t < B_t\} \\ &= E[V|H_{t+}] \end{aligned} \quad (3)$$

Thus, transaction prices form a martingale. From this observation, flow a number of immediate conclusions. Since reasonably behaved martingales such as this one converge, the absolute differences between transaction prices must get small. As long as trade continues, it must be the case that the spread gets small and that the informational difference between the informed traders and the market gets small.

A number of comparative statics results are readily obtained. At a point in time, an increase in the probability of informed arrival or an increase in the precision of private information increases the spread. As the elasticity of uninformed demand and supply increases, the spread increases as well. It is important to note, however, that these results hold only at a point in time—when the probability of informed trade increases, the rate at which trade reveals private information increases reducing spreads in the future.

The uninformed valuation plays a crucial role in the model. If the uninformed valuation varies little from the mean, then it is quite possible that the only bid and ask prices satisfying the condition are, respectively, the lowest and highest possible realizations of V . In this case, there is no trade and the market shuts down. On the other hand, if there is significant variation, so that the uninformed demand and supply are inelastic, then interior solutions for the quotes are guaranteed.

Canonical Example

The most common implementation of a Glosten–Milgrom model assumes that uninformed demand

and supply are perfectly inelastic and equally likely, the terminal value V has a two-point distribution and informed traders know what value of V will be realized. Without losing much generality, the two possible values of V can be taken to be zero and one. Define α to be the probability that an informed trader arrives in any time period. If p is the probability, conditional on past history, that the realization of V is one, then the conditional probability of a buy is $\alpha p + 0.5(1 - \alpha)$ and the conditional probability of a sell is $\alpha(1 - p) + 0.5(1 - \alpha)$. The ask and bid prices are thus

$$\begin{aligned} A &= P\{V = 1|\text{buy}\} = P\{\text{buy}|V = 1\}p / P\{\text{buy}\} \\ &= \frac{(\alpha + 0.5(1 - \alpha))p}{\alpha p + 0.5(1 - \alpha)} \\ B &= P\{V = 1|\text{sell}\} = \frac{0.5(1 - \alpha)p}{\alpha(1 - p) + 0.5(1 - \alpha)} \end{aligned} \quad (4)$$

The spread is thus $\alpha p(1 - p) / (P\{\text{buy}\}P\{\text{sell}\})$. Ignoring the denominator, which is approximately 0.25, the spread is increasing in the unresolved variance of V , $p(1 - p)$, and the probability of informed trade, α .

This model has particularly tractable transaction price dynamics. Recalling that transaction prices are updated expectations, it is readily seen that, denoting by p^+ the updated probability, and letting Q be a trade direction indicator (+1 for buy at ask and -1 for sell at bid), the following holds:

$$\frac{p^+}{1 - p^+} = \left(\frac{p}{1 - p} \right) \left(\frac{1 + \alpha}{1 - \alpha} \right)^Q \quad (5)$$

Assuming that, initially, it is equally likely that V be high or low, and denoting by p_t the revised probability that V is one, after t transactions, it is immediate that

$$\ln \left(\frac{p_t}{1 - p_t} \right) = \ln \left(\frac{1 + \alpha}{1 - \alpha} \right) \{Q_1 + \dots + Q_t\} \quad (6)$$

Conditional on V , the log odds ratio is proportional to a random walk with expected increment $\alpha(2V - 1)$. The larger the probability of informed trade is, the faster the log odds ratio increases in the case $V = 1$ and decreases in the case $V = 0$. The larger α is, the larger is the initial spread, but the faster the information gets impounded in prices and the faster the spread will fall.

In this model, expectations will not converge to one or zero in finite time. However, the convergence to almost one or zero can be quite fast. Let T_N be the first time that the log odds ratio hits N in the case $V = 1$ and $-N$ in the case $V = 0$, starting from $p_0 = 0.5$. Straightforward calculations show that the expectation of this stopping time is $N/[\alpha \ln((1 + \alpha)/(1 - \alpha))]$. For example, if the threshold odds ratio is 0.99/0.01, then N is less than 5. Setting $N = 5$, and letting α be 0.2, the expected first passage time is roughly 62 trades. The spread at these threshold odds and with α equal to 0.2 is 0.008. Setting α to 0.1 increases the expected number of trades to 250. The spread at these threshold odds and $\alpha = 0.1$ is 0.004. Thus, a stock with even moderate trading will reveal private information relatively rapidly, and the spread will decline quickly.

Relating the expected first passage time and the spread at the first passage time indicates an interesting trade-off. As the percentage of informed trading goes up, the initial spread increases, yet the speed with which the spread declines goes up as well. For $\alpha = 0.2$, the spread starts out at 0.2, but declines rapidly, becoming near zero with fewer than 100 expected transactions. In contrast, when $\alpha = 0.05$, the initial spread is 0.05, yet it takes an expected 300 trades to become minimal.

This raises intriguing questions about the welfare effects of informed trading; but these are not issues that this example of a Glosten–Milgrom model can handle. Since the uninformed trade, no matter what the spread, informed profit is merely uninformed loss and the total welfare is unaffected by how much informed trade there is. The spread is often related to a welfare measure, but this requires a questionable value judgment—informed are not entitled to their profits. To measure the welfare loss associated with informed trade, a model must incorporate elastic trade on the part of the uninformed.

Example with Elastic Uninformed Trade

The literature does not offer an analysis of transaction price dynamics with elastic uninformed trade. The following is a tractable model. As in the model above, the informed arrive with probability α , and know the terminal value. An uninformed trader arrives with private valuation, M , and buys if M exceeds the ask, sells if M is below the bid, and leaves otherwise.

Market makers do not know the private valuation, but know that if the current estimate of the security's value is p , then an uninformed trader's valuation has the following distribution:

$$P\{M < t\} = \frac{t(1 - p)}{t(1 - p) + p(1 - t)}; \quad 0 < t < 1, \quad 0 < p < 1 \quad (7)$$

In this case, the probability of a buy, when the current valuation is p and the offer is A is $\alpha p + (1 - \alpha)P\{M > A\}$. The probability of a buy given that V is one is $\alpha + (1 - \alpha)P\{M > A\}$ where $P\{M > A\} = p(1 - A)/[A(1 - p) + p(1 - A)]$ from equation (7). The ask, A , is the solution to

$$A = \frac{p(\alpha + (1 - \alpha)P\{M > A\})}{\alpha p + (1 - \alpha)P\{M > A\}} \quad (8)$$

$A = 1$ is one solution, but this will lead to no trade. Another solution is $A = p/(1 - 2\alpha(1 - p))$, as long as this is less than one and greater than zero, which is true if and only if $\alpha < 0.5$. Similarly, on the bid side, $B = p(1 - 2\alpha)/(1 - 2\alpha p)$ is the solution as long as $\alpha < 0.5$. If α exceeds 0.5, the market does not open since $A = 1$ and $B = 0$ are the only feasible solutions.

Because of assuming elastic uninformed trade, the initial spread is larger by the factor $1/(1 - \alpha)$. As the dealer increases the spread, he or she loses less to the informed, per trade, but as uninformed with less-extreme valuations drop out, the probability of transacting with an informed trader increases. This requires a greater widening of the spread.

In this model, not every arrival leads to a trade. The probability that an uninformed trader arrives and decides not to trade is α , precisely the probability of an informed trade. This model also has convenient dynamics. Conditional on V , the log odds ratio is $-\ln(1 - 2\alpha)$ times a random walk with drift $(2V - 1)\alpha$.

Assumptions and Extensions

One feature of the model leads to its immediate refutation—trades are for a single quantity. Several papers have extended the basic analysis to multiple trade sizes. Two possible trade sizes is considered by Easley and O'Hara [3], while Glosten [5] considers a continuum of trade sizes. Glosten [6] analyzes

continuous trade sizes in an electronic limit order book (see **Limit Order Markets**). Interestingly, there is evidence in [8] that the number of trades, as opposed to quantity is what contributes to volatility. Furthermore, [1] shows that a Kyle model ([9]; also see **Kyle Model**) with a continuum of allowable trades can, under some conditions, be thought of as a temporal aggregation of a dynamic Glosten–Milgrom model with a strategic informed trader.

One unreasonable assumption of the model is that the bid and offer are determined by a zero-profit assumption. The assumption implies that there is no compensation for the time and effort market making requires. The reason for the assumption is that the analysis can then focus on only the informational source of the spread. It is easy to extend the model to include compensation for market-maker opportunity (and other) cost by specifying that the bid, for example, satisfy $B = E[V|Z < B] - c$, where c is the economic cost that needs to be covered. With this more realistic specification, it is now apparent that the spread consists of two components—the cost component and the adverse selection component.

When there is no cost component, the martingale property of transaction prices implies that there will be no serial correlation in price changes. When there is only a cost component, however, it is easy to see that transaction prices will bounce back and forth between bid and ask, inducing negative serial correlation in price changes. That the different spread components lead to different transaction price dynamics informs empirical investigations of the spread (see **Adverse Selection**).

A strong assumption of the model is that the existence of informed traders is common knowledge. This is relaxed, first in [4] and then in a series of papers by Easley, O'Hara, and coauthors, in which the *probability of informed trade* (PIN) is theoretically derived and empirically investigated (see **Probability of Informed Trading**).

While the model is described in terms of competing market makers, it is somewhat more general than that. In particular, the model is not necessarily inconsistent with modeling trade on the New York Stock Exchange, or even an electronic limit order book. In the first case, the competing providers of liquidity are the specialist, floor brokers, and limit order submitters. In the second, limit order submitters com-

pete to provide the quote. Significantly, however, the model does not consider the trader choice between using a market or limit order, an important feature of trading on the NYSE and electronic limit order book markets (see **Adverse Selection; Limit Order Markets**).

Two survey papers on market microstructure, [10] and [2], are recommended. The first is stronger on a survey of empirical analyses, while the second is stronger on modeling issues.

LAWRENCE R. GLOSTEN

Kyle Model

The Kyle model [13] provides a tractable framework in which liquidity and the informativeness of prices can be measured. It played a key role in the proliferation of research papers on heterogeneous information that occurred in the past two decades.^a The model formalizes the explanation of liquidity given by Treynor [6]—reprinted as [14]—who observes that “the liquidity of a market . . . is inversely related to the average rate of flow of new information . . . and directly related to the volume of liquidity-motivated transactions.” These relationships are captured in “Kyle’s lambda”.

The Kyle model describes the price of a single risky asset over a time period $[0, 1]$. A risk-free asset is used as the numeraire, so the risk-free rate is zero. In the original model, there is a single trader with private information. An announcement is made at date 1 that reveals the information of this trader, and he/she is able to liquidate his/her position at date 1 at the revealed value. The “liquidity-motivated transactions” described by Bagehot [6] are modeled as random trades (by “liquidity traders” or “noise traders”) that are independent of the asset value. The trades of the informed and liquidity traders are “batched” and submitted to risk-neutral competitive market makers.^b The market makers trade on their own accounts to clear the market, and because of competition and risk neutrality, the clearing price is the expected value of the asset, conditional on the information in the order flow.

An important feature of the Kyle model is the strategic behavior of the informed trader, that is, he/she considers the impact his/her orders have on the market price. This assumption avoids the “schizophrenia” of traders who believe they have no impact on market prices yet understand that prices reflect their private information, which, as Hellwig [10] notes, prevails in some competitive rational expectations models.

Single-period Kyle Model

In the single-period model, trading occurs only at date 0. Before trading, the single informed trader observes a normally distributed random variable $\tilde{v}$ with mean $\bar{v}$ and variance σ_v^2 . The informed trader

chooses an order $\tilde{x}$ depending on $\tilde{v}$. Noise traders submit an order $\tilde{z}$ that is independent of $\tilde{v}$ and normally distributed with mean 0 and variance σ_z^2 . Market makers observe $\tilde{y} \equiv \tilde{x} + \tilde{z}$ and set the price equal to $\tilde{p} = E[\tilde{v}|\tilde{y}]$. At date 1, the value $\tilde{v}$ is revealed to the market, and the asset can be traded in arbitrarily large quantities at the price $\tilde{v}$. Thus, the informed trader’s profit is $\tilde{x}(\tilde{v} - \tilde{p})$, and his/her objective is to maximize the expected profit.

There is a unique “linear equilibrium”. Linearity means that $\tilde{p} = \mu + \lambda\tilde{y}$ and $\tilde{x} = \alpha + \beta\tilde{v}$, for constants μ , λ , α , and β . Equilibrium means the following:

- (A) Given α and β , pricing satisfies Bayes’ rule, that is, $\mu + \lambda\tilde{y} = E[\tilde{v}|\tilde{y}]$.
- (B) Given μ and λ , the insider’s strategy is optimal, that is,

$$\alpha + \beta\tilde{v} = \operatorname{argmax}_x E[x(\tilde{v} - \mu - \lambda(x + \tilde{z}))|\tilde{v}] \quad (1)$$

Note that optimality in (B) is among all possible demands x , including nonlinear functions of $\tilde{v}$. Linearity implies that $\tilde{v}$ and $\tilde{y}$ are jointly normal, so $\lambda = \operatorname{cov}(\tilde{v}, \tilde{y})/\operatorname{var}(\tilde{y})$. Using this fact and solving the optimization problem in (B), it is straightforward to calculate that the unique linear equilibrium is given by $\mu = \bar{v}$, $\alpha = -\beta\bar{v}$, $\beta = \sigma_z/\sigma_v$, and $\lambda = \sigma_v/(2\sigma_z)$. The unconditional expected profit of the informed trader is $\sigma_v\sigma_z/2$.

Kyle [13] defines the reciprocal of λ as the “depth” of the market. It measures the number of shares that can be traded, causing only a unit change in the price. The formula for $1/\lambda$ encapsulates Bagehot’s intuition: the depth of the market is proportional to the amount of noise trading as measured by σ_z and inversely proportional to the amount of private information as measured by σ_v .

Dynamic Kyle Model

A trader who recognizes that his/her trades impact the market price will typically want to execute a trade in small pieces, walking up or down the market supply curve. The single-period model gives the informed trader only one opportunity to trade, which is an unnatural constraint. Relaxing this constraint

enables one to examine how the dynamic optimization of the informed trader affects the evolution of liquidity over time. The general conclusion is that the informed trader spreads his/her trades over time in a manner that has the effect of smoothing liquidity intertemporally. We return to this issue in the final paragraph.

Kyle [13] analyzes a discrete-time N -period version of the model, assuming that the noise trades in each period are independent normally distributed variables with variance $\sigma_z^2 \Delta t$, where $\Delta t = 1/N$ is the length of each period. The variance of cumulative noise trades during the period $[0, 1]$ is again σ_z^2 . Kyle shows that the equilibria converge to the equilibrium of a continuous-time model in which the noise trades arrive as a Brownian motion with volatility σ_z .

The continuous-time model affords the informed trader the maximum flexibility in timing his/her trades. In the original continuous-time model, the single informed trader observes the normally distributed variable $\tilde{v}$ at date 0, and the asset trades at $\tilde{v}$ at date 1, as in the single-period model. The asset is traded continuously during $[0, 1]$. The number of shares Z held by noise traders is assumed to be a Brownian motion, independent of $\tilde{v}$, having volatility σ_z . Again, the variance of cumulative noise trades during $[0, 1]$ is σ_z^2 . At each date t , the informed trader chooses a number of shares X_t to hold. This choice depends on $\tilde{v}$ and the history of Z through date t .^c Market makers observe $Y \equiv X + Z$ and set the price P_t to be the expected value of $\tilde{v}$, conditional on the information in Y through date t .

The principal conclusions of the continuous-time model are as follows:

1. The price change at each instant is $dP_t = \lambda dY_t$, where $\lambda = \sigma_v/\sigma_z$. Thus, market depth is constant over time, and the depth of the market is only half of what it is when the informed trader is constrained to trade only once.
2. The price process is a Brownian motion with volatility σ_v . Constancy of the volatility means that information is incorporated into the price at a constant rate. The volatility does not depend on the level of noise trading σ_z .
3. All of the private information is incorporated into the price before the announcement date (the price converges to $\tilde{v}$ by date 1).
4. The expected profit of the informed trader is $\sigma_v\sigma_z$. Thus, the insider's expected profit is twice

what it is when he/she is constrained to trade only once. This implies that the expected losses of noise traders are also twice what they are in the single-period model.

5. The equilibrium informed trades are of order dt . This reflects the fact that the desired trades of a patient anonymous trader are optimally executed in small pieces.

To analyze the informed trader's optimization problem in this model, one must start with some guess about how P depends on Y . Two possible approaches are as follows: (i) conjecture $P_t = H(t, Y_t)$ for some function H and (ii) conjecture $dP_t = \mu_t dt + \lambda_t dY_t$ for nonrandom μ and λ . Either approach is feasible for the basic model. In some generalizations of the model, the first conjecture works, and in others the second works.^d Taking approach (ii), one can analyze the Hamilton–Jacobi–Bellman equation for the informed trader, using the price as the state variable, to deduce that μ must be zero and λ must be constant for the informed trader to have an optimum. When this is true, any continuous finite-variation strategy for the informed trader is optimal, provided the price is pushed to $\tilde{v}$ by the announcement date.

To deduce the value of λ , one can use the Kalman–Bucy filtering equation (*see Filtering*). Alternatively, in the basic model, one can reason as follows: because the price is always the conditional expectation of $\tilde{v}$, it is a martingale, given market makers' information. Because $dP = \lambda dY$, Y must also be a martingale relative to market makers' information. Given that dX is of order dt , it follows that the volatility of Y is the volatility of Z . Thus, Y is actually a Brownian motion with volatility σ_z , relative to the market makers' information. In particular, Y_1 is normally distributed with mean zero and variance σ_z^2 . Given that $\tilde{v} = P_0 + \lambda Y_1$, it follows that $P_0 = \tilde{v}$ and $\lambda = \sigma_v/\sigma_z$.

The informational advantage of the informed trader in this model can be summarized as follows. The price process appears to be a Brownian motion to market makers and the rest of the market. However, the informed trader knows its date 1 value $\tilde{v}$. Thus, to the informed trader, the price process is a Brownian bridge. The informed trader's equilibrium trading strategy is precisely the drift of a Brownian bridge:

$$dX_t = \frac{\sigma_z}{\sigma_v} \left(\frac{\tilde{v} - P_t}{1 - t} \right) dt \quad (2)$$

For general (i.e., nonnormal) continuous distributions of the asset value, the result of constant depth generalizes to λ being a martingale, given market makers' information. For example, if the asset value is lognormally distributed, then the equilibrium price process is a geometric Brownian motion: $dP = \lambda(P) dY = \phi P dY$ for constant ϕ [2]. This martingale property is robust to time-varying liquidity trading and a flow of information to the informed trader [5] but not to risk aversion [7, 12] or to the presence of multiple informed traders [4, 8, 11].

Acknowledgments

We are grateful to Pete Kyle for helpful comments.

End Notes

^aThe paper of Kyle [13] was the seventh most widely cited finance paper during the 1990s, according to Arnold *et al.* [1].

^bThe assumption that orders are batched is unimportant if liquidity trades are small and arrive frequently. This is established by Back and Baruch [3], who analyze a discrete-trade/Poisson model, which can be interpreted as a Glosten–Milgrom [9] model with explicit optimization by the informed trader. They show that the equilibria of the Glosten–Milgrom model converge to the equilibrium of a continuous-time Kyle model as the arrival rate of liquidity trades converges to infinity and the size of individual liquidity trades converges to zero.

^cThe informed trader can implicitly observe Z by observing the price and backing out the influence of X on the price.

^dA third approach is useful in the case of an informed trader with CARA utility: take $P_t = H(t, U_t)$ where $dU_t = \kappa_t dY_t$ for some function H and a nonrandom κ [7].

Probability of Informed Trading

The extent of private information in markets is a critical determinant in the price formation process. By modeling the trading process and the market maker's learning process, we can use trade data to make inferences about this private information, or more precisely, about the probability of informed trading (PIN). The extent of private information affects bid and ask prices and, hence, the available liquidity in an asset. Perhaps more importantly, the effect of PIN transcends pure market microstructure issues, as evidence suggests that PIN affects the required rate of return on stocks.

The PIN Model

In a series of papers, Easley *et al.* model a market in which a competitive market maker trades a risky asset with informed and uninformed traders [4–8]. As a simple example, consider the sequential trade tree diagram shown in Figure 1. Trade occurs over $t = 1, \dots, T$ discrete trading days and, within each trading day, trade occurs in continuous time. Information events occur between trading days with probability α . When an information event occurs, it is either bad news, with probability δ , or good news with probability, $1 - \delta$. Good news at date t is that the asset is worth $\bar{V}_t$, and bad news is that it is worth V_t .

During any trading day, orders arrive at the market according to Poisson processes. The market maker sets prices to buy or sell throughout the day, and then executes orders as they arrive. Traders informed of bad news sell and those informed of good news buy. Orders from the informed traders follow a Poisson process, with daily arrival rate μ . Uninformed traders trade for liquidity reasons. Buy and sell orders from uninformed traders arrive at the market according to independent Poisson processes, with daily arrival rates ϵ_b for buy orders and ϵ_s for sell orders. If an order arrives at some time, the market maker observes the trade (either a buy or a sale), and he/she uses this information to update his/her beliefs. New prices are set, trades evolve, and the price process

moves in response to the market maker's changing beliefs.

We can use the model parameters to compute the probability that the opening trade on a day is information based, PIN, as

$$\text{PIN} = \frac{\alpha\mu}{\alpha\mu + \epsilon_b + \epsilon_s} \quad (1)$$

where $\alpha\mu + \epsilon_b + \epsilon_s$ is the arrival rate for all orders and $\alpha\mu$ is the arrival rate for information-based orders. Thus, the ratio is the fraction of orders that arise from informed traders or the probability that the opening trade is information based.

The model is quite flexible and allows for extensions with greater complexity in the trading and information processes. Easley *et al.* [3], for instance, present a dynamic extension with time variation in the traders' arrival rates.

Estimating the PIN Model

Suppose that we now view this problem from the perspective of an econometrician. If we, like the market maker, can observe the sequence of trades, we can use this to estimate the structural model *via* maximum likelihood. That is, we can determine the probability of information-based trading in a given stock.

The first step in the estimation is to note that the total number of buys and sells per day is a sufficient statistic for the trade data. This occurs because of the assumption that arrivals follow independent Poisson processes. The likelihood function induced by this model for the total number of buys and sells on a single trading day is

$$\begin{aligned} \mathcal{L}((B, S)|\theta) = & \alpha(1 - \delta)e^{-(\mu + \epsilon_b + \epsilon_s)} \frac{(\mu + \epsilon_b)^B (\epsilon_s)^S}{B!S!} \\ & + \alpha\delta e^{-(\mu + \epsilon_b + \epsilon_s)} \frac{(\mu + \epsilon_s)^S (\epsilon_b)^B}{B!S!} \\ & + (1 - \alpha)e^{-(\epsilon_b + \epsilon_s)} \frac{(\epsilon_b)^B (\epsilon_s)^S}{B!S!} \quad (2) \end{aligned}$$

where (B, S) is the total number of buys and sells for the day and $\theta = (\mu, \epsilon_b, \epsilon_s, \alpha, \delta)$ is the parameter vector. This likelihood function is a mixture of three Poisson probabilities, weighted by the probability of having a “good news day” $\alpha(1 - \delta)$, a “bad news day” $\alpha\delta$, and a “no news day” $(1 - \alpha)$.

The model assumes that each day the arrivals of an information event and trades, conditional on information events, are drawn from identical and independent distributions. Thus, the likelihood function for T days is a product of the above likelihood over days. The log likelihood function, after dropping a constant term and rearranging, can be written as

$$\begin{aligned} \mathcal{L}((B_t, S_t)_{t=1}^T | \theta) &= \sum_{t=1}^T [-\varepsilon_b - \varepsilon_s + M_t (\ln x_b + \ln x_s) \\ &\quad + B_t \ln(\mu + \varepsilon_b) + S_t \ln(\mu + \varepsilon_s)] \\ &\quad + \sum_{t=1}^T \ln \left[\alpha(1 - \delta) e^{-\mu} x_s^{S_t - M_t} x_b^{-M_t} \right. \\ &\quad \left. + \alpha \delta e^{-\mu} x_b^{B_t - M_t} x_s^{-M_t} + (1 - \alpha) x_s^{S_t - M_t} x_b^{B_t - M_t} \right] \end{aligned} \quad (3)$$

where $M_t = \min(B_t, S_t) + \max(B_t, S_t)/2$, $x_s = \frac{\varepsilon_s}{\mu + \varepsilon_s}$, and $x_b = \frac{\varepsilon_b}{\mu + \varepsilon_b}$. The factoring of $x_b^{M_t}$ and $x_s^{M_t}$ increases the computing efficiency and reduces the truncation error. This is particularly important for stocks with a large number of buys and sells as it avoids computation of small fractions (arrival rates) taken to large powers (numbers of trades).

The likelihood function (3) depends upon the number of buys and sells per day. In the United States, the most widely available high-frequency data sets do not contain information about the underlying orders, only the resulting transactions. Therefore, researchers rely on algorithms such as the Lee and Ready [10] algorithm, which mainly uses trade placement relative to the current bid and ask quotes to determine trade direction.

Easley *et al.* [4] obtain yearly PIN estimates for all New York Stock Exchange (NYSE)-listed stocks. They find that PIN is on average 0.19 across stocks and its cross-sectional standard deviation is 0.057. That is, for an average stock, 19% of trades are motivated by private information.

Applications

The estimates of the model's structural parameters can be used to construct the theoretical opening bid and ask prices. As is standard in microstructure models, the market maker sets trading prices such that his/her expected losses to informed traders just offset his/her expected gains from trading with uninformed traders. This balancing of gains and losses gives rise to the bid–ask spread. The opening spread is easiest to interpret if we express it explicitly in terms of PIN. In the case where the uninformed are equally likely to

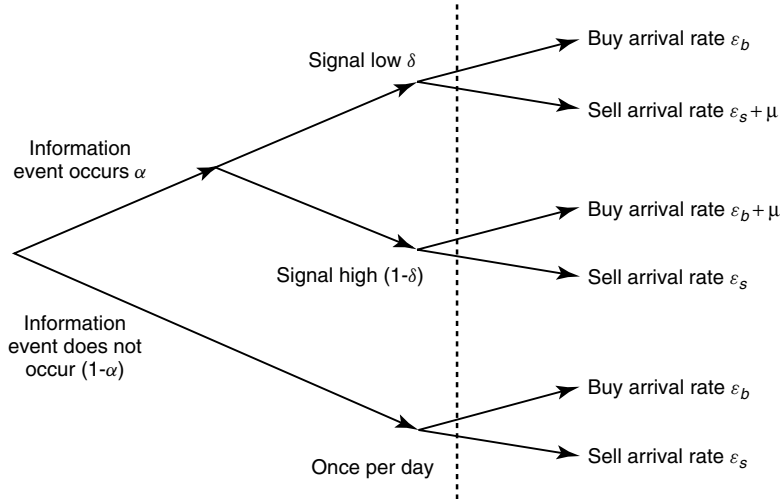

Figure 1 Tree diagram of the trading process. α is the probability of an information event, δ is the probability of a low signal, μ is the rate of informed trade arrival, ε_b is the arrival rate of uninformed buy orders, and ε_s is the arrival rate of uninformed sell orders. Nodes to the left-hand side of the dotted line occur once per day

buy and sell ($\varepsilon_b = \varepsilon_s = \varepsilon$) and news is equally likely to be good or bad ($\delta = 0.5$), the percentage opening spread is

$$\frac{\Sigma}{V_t^*} = \text{PIN} \frac{(\bar{V}_t - \bar{V}_t)}{V_t^*} \quad (4)$$

where Σ is the spread, ask minus bid price, and V_t^* is the unconditional expected value of the asset given by $V_t^* = \delta \bar{V}_t + (1 - \delta) \bar{V}_t$. The opening spread is therefore directly related to the probability of informed trading. Note that if PIN equals zero, because of the absence of either new information ($\alpha = 0$) or traders informed of it ($\mu = 0$), the spread is also zero. This reflects the fact that only asymmetric information affects spreads when market makers are risk neutral. Neither the estimated measure of information-based trading nor the predicted spread is related to market maker inventory because these factors do not enter into the model. Instead, these estimates represent a pure measure of the risk of private information.

Indeed, Easley *et al.* [8] and [4] find a strong relationship between PIN and the opening bid–ask spreads, consistent with the predictions of the model. In addition, PIN is negatively related cross-sectionally to variables such as firm size and the level trading activity and positively related to the level of insider and institutional holdings [1].

Informational asymmetry has implications for a firm's cost of capital. An increase in PIN represents a risk not only to the market maker but also to the uninformed investors who cannot adjust their portfolios to take the private information into account. Therefore, uninformed investors would need to be compensated to invest in high PIN stocks. Easley and O'Hara [9] formalize this notion in a rational expectations model and show that more private information and less public information lead to higher expected returns. Easley *et al.* [4] find that a difference in PIN of 10 percentage points (about 2 standard deviations) between two stocks leads to a difference in expected returns of 2.5% per year.

The PIN variable also represents a straightforward control or interaction variable for researchers interested in the impact of a third variable on, say, stock prices. As an example, Duarte *et al.* [2] find that the effect of regulation fair disclosure on a firm's cost of capital is negative related to PIN, which is consistent with the notion that high PIN firms benefit more from decreases in the informational asymmetry resulting from increased disclosure.

SOEREN HVIDKJAER

Roll Model

In his 1984 article entitled “A Simple Implicit Measure of the Effective Bid–Ask Spread in an Efficient Market”, Roll [4] developed a model that made it possible to measure an estimate of the bid–ask spread. This estimate depended only on the first-order serial covariance of price changes over time. As one of the first theoretical models to estimate the bid–ask spread, Roll’s model has served as a strong foundation upon which many future expansions and improvements have emerged to estimate the spread and its determinants.

Bid–Ask Bounce

One of the key concepts considered in the development of the Roll model is the idea of a “bid–ask bounce”. When a trade is undertaken by a market maker, it is generally executed at a price different from the actual market value of the asset. Instead a trader’s purchase from the market maker will be completed at the market maker’s ask price, while a sale to a market maker will be completed at the market maker’s bid price. The difference between the ask and the bid prices is referred to as the *spread*.

To estimate the bid–ask spread using the observed transaction prices, Roll assumed that the probability that the next transaction is a buy is equal to the probability of it being a sell. If the market maker’s previous transaction was a purchase at the bid price, then there is an equal probability that the next transaction will be executed at either the bid or the ask. The same logic holds if the market maker’s previous transaction were to be a sale to a customer at the ask price. For example, assume that the market maker’s trade at time $t - 1$ was executed at the ask price, then there is an equal probability that the next trade at time t will be at the bid or the ask. If at time t , the trade is again at the ask, then the change in price is zero. However, if it is at the bid, then the change in price is equal to the spread “ $-s$ ” (Figure 1), where s is the difference between the bid and the ask prices.

Figure 1 shows the possible sequence of trades given that a trade at time $t - 1$ takes place at the ask price. The fundamental value of the asset, P^* , is at the midpoint between the bid and the ask prices and

it follows a random walk. $P_t^* = P_{t-1}^* + \tilde{\eta}_t$, where $\tilde{\eta}_t$ is white noise such that

$$E[\eta_t] = 0, \text{Var}[\tilde{\eta}_t] = \sigma^2$$

$$\text{and } E[\tilde{\eta}_t \tilde{\eta}_{t-s}] = 0 \quad \forall t \neq s \quad (1)$$

Given Roll’s assumption that it is equally likely for the next trade to be at the bid or the ask, the probabilities associated with successive price changes are given in Table 1. The probabilities are based on the observation that there are a total of eight paths from $t - 1$ to $t + 1$, starting from either the ask or the bid prices. Therefore, each path has a probability of $1/8$. Each path is associated with joint price changes of ΔP_t (where $\Delta P_t = P_t - P_{t-1}$) and ΔP_{t+1} that is a combination of 0 , s , and $-s$. For example, there is only one path for $\Delta P_t = 0$ and $\Delta P_{t+1} = -s$ starting from the ask price at $t - 1$. Hence, the probability of this joint event is $1/8$. Similarly, we can find the probabilities for each combination of price changes.

On the basis of Table 1, the serial covariance of price changes $SCov(\Delta P_t, \Delta P_{t+1})$ is $-s^2/4$ and $s = 2\sqrt{-SCov(\Delta P_t, \Delta P_{t+1})}$. With this equation, an estimate of the spread can be obtained based on the estimate for the serial covariance of successive price changes. The standard serial covariance estimator used is the mean cross product: $\widehat{SCov} = \frac{1}{n} \sum_{t=1}^n \Delta P_t \Delta P_{t+1} - \overline{\Delta P}^2$, where $\overline{\Delta P}$ is the sample mean of P_t . Initially, Roll’s model was developed to estimate bid–ask spread from transaction prices. However, there are some drawbacks to its practical use. Some of the model’s assumptions are very specific and may not carry over to real-life application. For example, the Roll estimator is based on the assumption that the stock’s fundamental value follows a random walk and that there is an equal probability that the next trade will be a buy or sell. Hence, the probability of a future trade at the ask or the bid prices is independent of the prior trade direction. However, there is some evidence that the probability of a trade continuation might be different from a trade reversal. The model also assumes that the spread is entirely due to order processing costs and does not include adverse selection or inventory costs, implying that ΔP_t is independent of whether the transaction at time t is at the bid or the ask. Harris [2] provided a detailed analysis of the small sample properties of the Roll serial covariance estimator

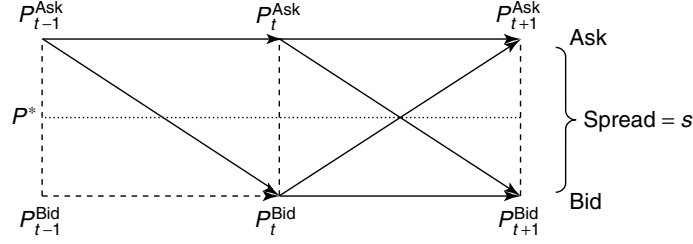

Figure 1 Possible sequence of trades given that the trade at time $t - 1$ takes place at the ask price (based on Roll [4])

Table 1 Joint price change distribution for ΔP_t and ΔP_{t+1} (based on Roll [4])

		ΔP_t		
		$+s$	0	$-s$
ΔP_{t+1}	$+s$	0	1/8	1/8
	0	1/8	1/4	1/8
	$-s$	1/8	1/8	0

for the bid–ask spread. He concluded that the serial covariance estimator is very noisy in daily data and is biased downward in small samples. Using weekly data would reduce the bias, but it will also lead to smaller sample sizes. He also found that the bias from Jensen’s inequality is very serious in daily and weekly data.

Bid–Ask Spread-induced Bias in Volatility Estimator

Stock return volatility estimates based on transaction prices will lead to an upward bias due to the bid–ask bounce. The transaction price, P_t , consists of the unobserved “true” price P_t^* , and the half-spread, $+\frac{s}{2}$ if the transaction was at the ask price and $-\frac{s}{2}$ if the transaction was at the bid price. Therefore, $\tilde{P}_t = P_t^* + \frac{s}{2} \tilde{D}_t$, where $\tilde{D}_t$ is the buy/sell indicator, which is equal to 1 with probability 0.5 (buyer-initiated trade) and equal to -1 with probability 0.5 (seller-initiated trade).

If we assume that P_t^* evolves as a random walk, such that $P_t^* = P_{t-1}^* + \tilde{\eta}_t$, then the variance of the price change based on transaction prices can be written as

$$\begin{aligned} \text{Var}(\Delta P_t) &= \text{Var}(\tilde{\eta}_t) + \text{Var}\left(\frac{s}{2} \Delta \tilde{D}_t\right) \\ &= \sigma^2 + \frac{s^2}{4} \text{Var}(\Delta \tilde{D}_t) = \sigma^2 + \frac{s^2}{2} \quad (2) \end{aligned}$$

where $\Delta P_t = P_t - P_{t-1}$ and $\Delta \tilde{D}_t = \tilde{D}_t - \tilde{D}_{t-1}$.

Since the variance calculated using transaction prices will include both the variance from the bid–ask bounce as well as the actual price variance, the calculated variance will overstate the fundamental volatility by $\frac{s^2}{2}$.

The magnitude of the bid–ask bounce-induced volatility remains the same whether we look at short-interval (high-frequency) or long-interval (low-frequency) returns. However, volatility due to the bid–ask bounce becomes a larger proportion of the fundamental return volatility with a decrease in the return horizon. French and Roll [1] provided a variance estimator that is unbiased but noisy.

A Generalized Roll Model with Adverse Selection

Since the publication of Roll’s paper in 1984, there have been many related papers that relax some of the assumptions made by Roll, and others have used Roll’s model as a foundation to develop general models to include asymmetric information, inventory costs, price discreteness, and other microstructure related effects. We can generalize the Roll model to include the adverse selection cost as follows.

The unobserved fundamental value P_t^* is given as

$$P_t^* = P_{t-1}^* + \tilde{\eta}_t + (1 - \pi) \left(\frac{s}{2} \tilde{D}_t \right) \quad (3)$$

where $(1 - \pi)$ is the fraction of the half-spread due to adverse selection and $\tilde{\eta}_t$ is a serially uncorrelated public information shock. If the fraction of the half-spread due to order processing is π , then the

transaction price is given as

$$P_t = P_t^* + \pi \left(\frac{s}{2} \tilde{D}_t \right) \quad (4)$$

If π is set to equal 1, we get back to the original Roll model. Under this model, it can be shown that $SCov(\Delta P_t, \Delta P_{t-1}) = -\pi \frac{s^2}{4}$. Hence, only when $\pi = 1$ (i.e., no adverse selection) can we obtain an unbiased estimator of “ s ” using the $SCov(\Delta P_t, \Delta P_{t-1})$ as in [4]. A more detailed description of a generalized Roll model can be found in [3].

Summary

Roll’s 1984 article developed a relatively simple model to estimate the bid–ask spread based on observable trade prices. This model has been very useful in situations where direct bid–ask data were not available. The Roll model has been a foundation upon which several extensions and other models have emerged to estimate the spread and its determinants.

Call Auction Markets

Countless market structures exist for equity trading. Each is a variant of and/or a hybrid combination of four generics: (i) the continuous order-driven, agency market, (ii) the periodic order-driven call auction, (iii) the continuous quote-driven, dealer market, and (iv) the negotiated market (e.g., floor trading, upstairs block negotiation, and electronic negotiation). One of the common market mechanisms is the *call auction market*.

The distinguishing characteristic of a call auction is the batching of orders for simultaneous execution in a multilateral trade at a single clearing price, at a single point in time. This contrasts with continuous trading (either order or quote driven) where a trade can occur whenever a buy and a sell order match or cross in price.

At the specific point in time when a market is “called”, buy orders are sorted and the shares aggregated from the highest priced buy to the lowest, and sell orders are sorted and the shares aggregated from the lowest priced sell to the highest. The two arrays of aggregated shares are matched, and the clearing price is set at the value at which the largest number of shares will execute—where the aggregated number of shares to buy (which decreases with price) equals the aggregated number of shares to sell (which increases with price). Buy orders at the clearing price and higher execute, as do sell orders at this price and lower (further rules of order execution are used when the number of shares to buy does not match the number of shares to sell exactly). Because all orders execute at the common clearing price (not the price at which they have been placed), executable orders are generally price improved.

If the clearing price at the auction is determined as just described, the system is a *price discovery call*. If the clearing price is set elsewhere (exogenously), the system is a *crossing network*. The clearing price for an intraday crossing network is typically the midpoint of the bid and ask quotes posted by a major market center. The after-hours crosses typically use market closing prices. This article focuses on *price discovery* call auctions. For further discussion of the properties of call auction trading, see [4, 5] and [14], Chapter 4.

The Advent of Electronic Calls

Each of the four above-noted generic forms of trading can involve human-to-human interaction (either face-to-face on an exchange floor or via the telephone) and/or electronic technology. Call auction trading, however, predates electronic technology. One hundred and thirty eight years ago, the New York Stock Exchange was a call market. The Tel-Aviv Stock Exchange through the 1970s and the Paris Bourse, before it introduced its electronic, order-driven market in 1986, were also nonelectronic call auctions. Pressure from an increasing order flow and from competing continuous markets crowded out the non-electronic calls.

In the past two decades, call auction trading has made its re-entrance as an electronic marketplace. The electronic calls are being used, most notably, by Deutsche Börse; NYSE Euronext’s Paris, Amsterdam, and Brussels exchanges; the London Stock Exchange; SWX Swiss Exchange; and the Nasdaq Stock Market. The New York Stock Exchange opens and closes its markets with calls but, as of this writing, its calls are not fully electronic.

The electronic calls are not standalone systems but have been combined with continuous trading to create hybrid markets. With a hybrid structure, an investor can select among alternative trading venues depending on the size of his or her order, the liquidity of the stock being traded, and the investor’s own motive for trading.

Tempering Volatility at Market Openings and Closings

Because they consolidate orders and amass liquidity, call auctions have been used to sharpen price discovery. As such, they are generally run to open and to close a market, and to reopen a market that has been halted because of stressful market conditions. The opening is itself a time of stress because of the difficulty of translating overnight news into new share values. The closing is a time of stress because of trader impatience to “get the job done” before the trading session ends. The stress that characterizes openings and closings is apparent in the sharp accentuation of intraday volatility in the first and last minutes of a trading day [11].

Paris introduced electronic closing calls in 1996 and 1998 in response to derivative traders’ demand

for better closing prices. In 2004, Nasdaq introduced its electronic calls (which it refers to as its *Crosses*) for a similar reason. As reported in [11], “Nasdaq decided to introduce Closing Cross in Fall 2003 after a competing market, the American Stock Exchange, responding to a strongly expressed request from Standard & Poor’s for better closing prices, started planning a closing call of its own that would be used for Nasdaq stocks.”

The accentuation of volatility at market openings and closings has been well documented in the academic literature (relevant volatility studies include [1, 7–11, 16]). The ability of call auctions to contain this volatility and improve market quality has also been established [2, 11–13, 15]. Nevertheless, Ellul *et al.* [6] suggest that the call “suffers from a high failure rate to open and close trading especially when trading conditions are difficult.” The theoretical analysis of order submission to a call auction by Chakraborty *et al.* [3] also shows the difficulty of getting early order submission (a “bookbuilding” problem); these authors suggest that the effectiveness of a call depends on structural issues such as its transparency and whether or not it includes a market maker to “animate” bookbuilding.

Smaller Cap Stocks and Large Institutional Orders

The ecology of an order-driven market breaks down when it receives inadequate order flow. Call auction trading, because it amasses liquidity at fixed points in time, can help overcome this problem. Accordingly, call auctions are important for trading mid- and small-cap stocks (the Paris Bourse uses them for these issues).

Placing large, institutional-sized orders on a continuous, open book market is also problematic (disclosure of a large order before it executes fully can cause adverse price moves that raise execution costs). Order batching, by amassing liquidity and delivering price improvement, also mitigates this adverse effect.

Order Handling in Call versus Continuous Markets

Orders are handled differently in call auctions than in continuous trading:

- In continuous order-driven markets, limit orders set the prices at which market orders execute, and limit orders sitting on the book provide immediacy to market orders. In contrast, market orders in a call auction are nothing more than extremely aggressively priced limit orders. Specifically, a market order to buy has an effective price limit of infinity, and a market order to sell has an effective price limit of zero.
- Limit orders in continuous trading generally execute at the prices at which they have been placed. Because in call auction trading all orders execute at the common clearing price, the more aggressively priced limit orders are price improved. This encourages participants to price their orders more aggressively, which enhances market liquidity.
- All participants in a call auction wait until the next call for their orders to execute. Thus, market orders do not receive immediacy as they do in continuous trading.
- In continuous trading, limit orders supply liquidity and market orders dry up liquidity. This distinction does not apply in call auction trading. In a call auction, all participants supply liquidity to each other. However, if limit orders on the book are publicly displayed, those participants who place their orders early in the precall, order entry period are key contributors to liquidity creation (i.e., they animate bookbuilding).

Overview

Comprehensively viewed, imbedding call auctions in a continuous trading environment can have major positive benefits: most notably, lower volatility, lower execution costs, and sharper price discovery. The success of a call auction is not foreordained, however. To operate effectively, critical mass order flow must be received. Whether the requisite order flow is achieved depends critically on a call auction’s specific architectural design.

Limit Order Markets

The organization of trading in financial markets has undergone tremendous changes at the end of the twentieth century. In stock markets, electronic limit order books have progressively replaced floor and dealership markets. For instance, the Paris Bourse closed its floor and became a fully electronic limit order market in 1986. Bond and currency markets follow a similar evolution with the emergence of trading platforms such as EBS (FX) or E.speed and MTS (bond markets). This evolution has been a major impetus for academic research on limit order markets. This article provides a brief review of this research.

Market and Limit Orders

Limit orders and market orders (*see* **Order Types**) are the core engine of limit order markets. Limit orders specify a price and a number of shares. For instance, a limit order to buy (respectively sell) 500 shares of stock XYZ at \$10 means that the order submitter is willing to buy up to 500 shares at \$10 or less (respectively more). As they have a prespecified price, limit orders cannot always be matched with contra-side orders upon arrival. In this case, they are stored in a limit order book. They exit the limit order book when they are hit by subsequent orders or cancelled by the order submitter.

A market order specifies a number of shares to buy or to sell with no price limit. It is matched upon arrival with contra-side limit orders (e.g., a buy market order is matched with sell limit orders). The latter execute in sequence according to price priority and other rules (e.g., first-in first-out) for orders tied at the same price. Consider, for instance, the arrival of a buy market order for 1000 shares when the limit order book features sell limit orders at (i) \$10 (best ask price) for 500 shares, (ii) \$10.5 for 700 shares, and (iii) \$10.7 for 200 shares. The market order executes for 500 shares at \$10 and for the remaining 500 shares at the next best offer, \$10.5. Execution of limit orders is “discriminatory” in the sense that each limit order is filled at its own price.

Copeland and Galai [12] point out that limit orders are similar to options. For instance, a buy (sell) limit order at \$10 is similar to a put (respectively

call) option with a \$10 strike price. Indeed, it gives the possibility to other market participants to sell the security at \$10 when its value falls below \$10. These options are free. Yet, they can be written at a profit because, in contrast to regular options, they are sometimes exercised out-of-the money by traders who need immediate execution. Bid and ask prices can then be viewed as the strike prices that balance losses when limit orders execute in-the-money (are “picked off”) with gains when they execute out-of-the money [12]. Foucault *et al.* [18] argue, and show empirically, that the limit order book contains information on future price volatility since limit orders are options.

Limit order traders can reduce the likelihood of being picked off by monitoring their orders. Foucault *et al.* [19] analyze this monitoring decision in a model similar to that in [12]. Liu [32] extends this model to study the interactions between monitoring decisions and cancellations in a limit order market. He provides evidence that traders submitting limit orders actively monitor their orders to reduce the risk of being picked off.

The choice between limit and market orders hinges upon a trade-off between the gain of a limit order (a price improvement relative to standing quotes) and its costs, namely, the cost of nonexecution, the cost of being picked off, the cost of trading with better informed investors, monitoring costs, waiting costs [14], and submission fees. Harris and Hasbrouck [24] study the performance of actual limit orders. They find that buy (respectively sell) limit orders execute more frequently in the case of a price decline (respectively increase). Moreover, they also find that the opportunity cost of unfilled limit orders behind the best quotes is significant. Handa and Schwartz [23] use hypothetical limit and market orders. They find that the performance of filled (respectively unfilled) limit orders is higher (respectively smaller) than that of market orders. Unconditionally, the performance of each order type is identical. Overall, these findings suggest that the cost of being picked off and the cost of nonexecution are significant.

The optimal order submission strategy depends on each trader’s objective (e.g., whether the trader is constrained to trade a specific number of shares or not), his/her expectation regarding future order submissions, and the current state of the book. In turn, traders’ orders affect the state of the book and future order submission choices. Biais *et al.* [6] offer the

first empirical description of the interactions between the state of the limit order book and the order flow in a pure limit order market (the Paris Bourse). They uncover a *diagonal effect*: the frequency of an order of a given type (e.g., a buy market order) conditional on an order of the same type is higher than the unconditional frequency of this order. This observation is confirmed by subsequent empirical analyses of other markets [22, 35]. Biais *et al.* [6] also show that order submission strategies depend on the state of the limit order book in systematic ways. These observations paved the road for research about the effect of the state of the limit order book (e.g., the size of the bid–ask spread, the depth at the best quotes, etc.) on order submission choices (see, for instance, Beber, A. & Caglio, C. (2004). *Order Submission Strategies and Information: Empirical Evidence from the NYSE*. Unpublished manuscript, University of Lausanne; Ellul, A., Holden, C.W., Pankaj, J. & Jennings, R.H. (2003). *Determinants of Order Choice on the New York Stock Exchange*. Unpublished manuscript, Indiana University [22, 35]).

Ahn *et al.* [1] study the interactions between order submissions and transitory volatility. They find that traders use limit orders more frequently after a rise in transitory volatility. One possibility is that this increase in volatility reflects an increase in the bid–ask spread due to transient liquidity pressures. This increase in the bid–ask spread attracts limit order traders as providing liquidity becomes more profitable. Consistent with this interpretation, Biais *et al.* [6] find reversals in the size of bid–ask spreads after the arrival of large market orders. The speed of this reversal determines the resiliency of a limit order market to liquidity shocks and constitutes one important dimension of market liquidity. Degryse *et al.* [13] and Large [30] provide empirical analyses of the resiliency of limit order markets.

Wyart *et al.* [41] uncover a high positive correlation between the bid–ask spread and the volatility per trade in limit order markets. They show that this relationship is expected if both liquidity providers and liquidity takers follow order submission strategies with positive expected profits.

Models of Price Formation in Limit Order Markets and Empirical Tests

The limit order book can be described by the mapping between quotes in the book and the cumulative

quantity available at these quotes (e.g., in the previous example, the cumulative quantity offered for sale is 500 shares at \$10, 1200 shares at \$10.5, and 1400 shares at \$10.7). Naturally, a strand of research on limit order markets focuses on this mapping as it determines the cost of execution for traders submitting market orders and thereby market liquidity. In the previous example, execution costs are smaller other things being equal if the limit order book features, say, a cumulative quantity of 1200 shares at \$10.5 instead of only, say, 600 shares.

Glosten [20] considers a model in which some traders submitting market orders can be better informed on the payoff of a risky security than traders submitting limit orders. He shows that the quotes associated with a given cumulative quantity are equal to limit order traders' expectation regarding the payoff of the security conditional on the size of the next market order being larger than this cumulative quantity. For instance, if V is the payoff of the risky security, $Q(A)$ is the cumulative quantity offered at the ask price A , and X is the size of the incoming market order, then, in equilibrium, $Q(A)$ satisfies

$$A = E(V | X > Q(A)) \quad (1)$$

Thus, ask prices are upper tail conditional expectations. By symmetry, bid prices are lower tail expectations. This feature is closely related to the discriminatory execution of limit orders and does not obtain in earlier models of trading with asymmetric information [29]. It implies that buy market orders execute at a mark-up compared to sell market orders, even if the size of these orders is infinitesimal. That is, there is “*small trade bid ask spread*.”

Glosten [20] assumes perfect competition among limit order traders. Thus, the restrictions on quotes and cumulative quantities (e.g., equation (1)) derive from a zero profit condition for limit orders. Biais *et al.* [7] provide a more general analysis allowing for imperfect competition (see also [5]). Seppi [38], Viswanathan and Wang [40], and Parlour and Seppi [34] study the mapping between quotes and cumulative quantities in limit order markets in models without asymmetric information.

These models are static. Hence, they are silent on the determinants of the choice between market and limit orders. Cohen *et al.* [11] offer the first theoretical analysis of this choice. They uncover the “*gravitational pull effect*.” That is, when the bid–ask spread becomes tight, the benefit of a

price improvement with a limit order becomes small compared to the cost of nonexecution. Thus, traders are “pulled” to use market orders. This effect provides another explanation for the existence of a small trade bid–ask spread in limit order markets.

Execution probabilities are exogenous in [11]. Foucault [16] (Foucault, T. (1995). *Price Formation and Order Placement Strategies in a Dynamic Order Driven Market*. Working paper, Universitat Pompeu Fabra.), Parlour [33], Foucault *et al.* [17], Rosu [36], and Large [31] introduce dynamic models of trading in limit order markets in which execution probabilities are consistent with order submission choices in equilibrium. These models explain variation in order submission choices by variations in the state of the book and traders’ valuations for the security. Traders with high valuations submit more aggressive buy orders and traders with low valuations submit more aggressive sell orders. Thus, traders with extreme valuations are more likely to submit market orders and traders with intermediate valuations are more likely to submit limit orders.

Parlour [33] studies a one tick market. Upon arrival, buyers (respectively sellers) choose to submit a limit order at the bid (respectively ask) price or a market order. In this model, limit orders face a risk of nonexecution. In equilibrium, traders’ order placement decisions depend on the state of the limit order book on *both* sides. For instance, the decision to submit a buy limit order depends on the depth on the ask side because this depth will affect future sellers’ order submission choices. Moreover, the equilibrium features systematic patterns on order submissions. For instance, a sell market order is more likely after a sell market order than after a buy market order as found empirically in [6].

Foucault [16] focuses on the effect of price volatility on order submission choices. In this model, traders’ valuations for the security are distributed around a consensus value that follows a random walk. Thus, changes in traders’ valuations are positively correlated with changes in the consensus value. Consequently, buy (respectively sell) limit orders are more likely to execute when the consensus value decreases (respectively increases) than when it increases (respectively decreases). For this reason, limit orders are exposed to the risk of being picked off. Under simplifying assumptions (e.g., limit orders expire after one period), Foucault [16] characterizes order submission strategies

in closed-form. In equilibrium, the fraction of limit orders in the order flow and the bid–ask spread increase with the volatility of the consensus value. In contrast, limit orders fill rate decreases with volatility since market orders are less frequent when the bid–ask spread is large. Van Achter extends this model by considering the case in which limit orders have longer time to expiration (Van Achter, M. (2006). *A Dynamic Limit Order Market with Diversity in Trading Horizons*. Working paper, available at <http://ssrn.com/abstract=967610>).

Foucault *et al.* [17], Rosu [36], and Large [31] study the role of waiting costs. In these models, traders care about time to execution for limit orders since it determines their expected waiting cost. Foucault *et al.* [17] study the determinants of expected time to execution and the speed at which the bid–ask spread reverts to competitive levels after liquidity shocks. Rosu [36] introduces the possibility of cancellations and provides an explanation for the high cancellation rate observed in some markets (See for instance Hasbrouck, J. and Saar, G. (2002). *Limit orders and volatility in a hybrid market: the Island ECN*, Working paper, NYU). Large [31] proposes a new approach that exploits the fact that there must be as many filled limit orders as submitted market orders.

All these models obtain analytical results at the cost of strong assumptions. Goettler *et al.* [21] relax many of these assumptions while retaining the idea that changes in traders’ valuations and the consensus value drive variations in order submission choices. They use techniques from computational economics to numerically calculate the equilibrium of the limit order market for specific parameter values. They find that the diagonal effect is an equilibrium property of the limit order market. It arises because (i) there is persistence in the state of the limit order book (hence, traders submit similar orders) and (ii) it takes time for traders to take advantage of stale limit orders after large changes in the consensus value (as initially suggested by Hollifield *et al.* [26]).

Do the trade-offs considered in theories of limit order markets explain actual order submissions? Sandås [37] tackles this question by testing restrictions implied by Glosten’s [20] model for quotes, cumulative quantities, and changes in transaction prices using data from the Stockholm Stock Exchange. He rejects the model because actual limit order books are not deep enough to be explained by the

model. One possible explanation is that competition among limit order traders is imperfect (a feature absent in [20]). Another, related, possibility is that it takes time for the limit order book to replenish after liquidity shocks. Thus, trades occur when profit opportunities remain in the limit order book.

Hollifield *et al.* [26] test a more general formulation of [16]. Their model makes predictions about which type of orders (e.g., a buy limit order one tick below the best ask price) should *not* be observed for each state of the limit order book because they are suboptimal for all traders (whatever be their valuation). They build a test of the model by tracking these suboptimal orders. They reject the model because the expected payoffs on limit orders with low execution probabilities are too small compared to the expected payoffs of limit orders with higher execution probabilities. Thus, these limit orders with low execution probabilities should not be observed according to the model.

New Research Directions

Despite their widespread use in financial markets, little is known on the allocative efficiency of limit order markets. Empiricists often use measures of bid–ask spreads as a proxy for efficiency, presuming that larger bid–ask spreads are associated with greater inefficiencies. However, Goettler *et al.* [21] show that bid–ask spreads are poor proxies of actual gains from trade in limit order markets. Hollifield *et al.* [27] develop a methodology to empirically estimate the fraction of the maximum gains from trade that are achieved in the limit order market. They implement this methodology with data from the Vancouver Stock Exchange and find that about 90% of the maximum gains from trade are achieved.

A related question is the performance of limit order markets relative to other market structures. Viswanathan and Wang [40] and Back and Baruch [3] compare equilibrium outcomes in a market with discriminatory execution of limit orders and a market with uniform execution of limit orders (i.e., all limit orders eligible for execution execute at the execution price of the marginal share). In a model related to Glosten [20], Back and Baruch [3] identify conditions under which the equilibrium of the two markets is identical. Some authors (e.g., Baruch [4] and Boehmer *et al.* [9]) also study theoretically or

empirically the effects of trading rules in limit order markets (transparency, priority rules, tick size, etc.) on their performance (e.g., informational efficiency and liquidity).

Models of limit order trading often assume that informed traders submit market orders. Kaniel and Liu [28] relax this assumption and establish conditions under which informed traders use limit orders. Bloomfield *et al.* [8] find experimental evidence that informed traders use both market and limit orders. These findings imply that limit order books may contain information about future price movements. Anand *et al.* [2], Harris and Panchapagesan [25], (Irvine, P., Benston, G. & Kandel, E. (2000). *Liquidity Beyond the Inside Spread: Measuring and Using Information in the Limit Order Book*. Working paper, Emory University.), and Kaniel and Liu [28] provide empirical evidence consistent with this implication.

Theories of limit order placement assume that traders have rational expectations and choose their orders optimally in any circumstances. Several papers [10, 15, 39] (Ladley, D. & Reiner Schenk-Hoppé, K. (2007). *Do Stylised Facts of Order Book need Strategic Behaviour*. Working paper no. 383. National Centre of Competence in Research Financial Valuation and Risk Management.) study models of limit order trading with zero-intelligence traders. These traders submit random orders satisfying some minimal conditions (e.g., they do not violate traders' budget constraint). Interestingly, some empirical regularities of limit order markets (e.g., the diagonal effect) emerge even with zero-intelligence traders. Thus, the trading mechanics of these markets can in itself explain some of the properties of limit order markets, independently of the degree of sophistication for the traders.

Specialist Markets

A specialist market is defined as a hybrid market structure that includes an auction component (e.g., a floor auction or a limit order book) together with one or more designated market makers (“specialists”) who trade as dealers for their own account. The designated market makers have some responsibility for the market; for example, specialists are usually obligated to continuously post quotes with reasonable depth. In return, they get a preferential treatment, be it access to order flow, information about the state of the market, discounted trading fees, or direct monetary compensation from the exchange or the listed firm.

The New York Stock Exchange (NYSE) is considered the quintessential specialist market, and one can trace several important elements in this definition to the historical development of that market. The NYSE started as an auction market, and, prior to World War II, the most important function of the specialist was as a brokers’ broker, coordinating the trading process and maintaining a limit order book [20]. In other words, the auction component of the hybrid specialist system (which enables investors to trade directly with other investors) has always been a feature of this market structure, and it makes specialist markets distinct from pure dealer markets.

The dealer function of the specialists on the NYSE received greater emphasis as brokers sought speedy execution of orders and the importance of the affirmative obligation of specialists to assist in maintaining a fair and orderly market was stressed [20, 21]. It is the specialist’s presence that makes this market structure different from pure auction markets (e.g., call auctions, floor markets, or limit order books; see **Call Auction Markets** and **Limit Order Markets**). While some specialist markets mandate only one specialist, others allow (and even encourage) multiple designated market makers. On the NYSE, for example, there were competing specialists in 466 stocks when the 1933 Securities Act was passed, but their numbers decreased over the years and, by 1967, no NYSE-listed securities were traded by multiple specialists (see [18], pp. 337–338).

As securities markets around the world face extensive competition, one of the most important questions in market microstructure is whether there is a “best” market structure for all securities that will eventually dominate the landscape. While the specialist market

system was successful in the past, an interesting trend over the past two decades has been the adoption of such a market structure by derivatives exchanges and stock markets around the world for the trading of less active securities. Hence, the viability of this market structure suggests that it fulfills certain important needs of investors. In the following sections, a brief review of some theoretical work on specialist markets is provided, recent empirical evidence on the impact of adopting a specialist system is surveyed, and the manner in which specialists are compensated is discussed.

Theory

Much of the early literature about specialists dealt with the provision of liquidity by dealers without specific attention to whether or not they coexist with an auction mechanism. The manner in which dealers set prices is affected by such considerations as inventory control (see **Inventory Effects**) and information asymmetry in the market (see **Adverse Selection**). The unique hybrid structure of the specialist system, however, gives rise to additional complexity due to the strategic interaction between investors who want to use the auction component of the market (e.g., limit order traders) and the specialists.

Conroy and Winkler [6] show in a simple setting that competition from public limit orders forces the specialist to offer a narrower spread. Rock [16] provides an insightful analysis of the strategic interaction between limit order traders and the specialist when some investors in the market have private information. He notes that a trader who submits a limit order to the book does not know *ex ante* whether his or her order will be executed by a small order arriving from an uninformed trader or as part of a large order coming from an informed trader. What makes the specialist on the NYSE different from other traders is the ability to condition his or her participation as a dealer and the prices in which he or she transacts on the size of the arriving market order (due to the specialist’s control over the execution of trades).

The presence of the specialist imposes adverse selection on the limit order traders because he or she takes the smaller market orders (most likely uninformed and hence profitable) and leaves the larger market orders (which are more likely to be motivated by private information) to transact

against the book. Without the specialist, (uninformed) small market orders transact at worse prices because the *ex ante* nature of prices in the limit order book pools them together with the (informed) large market orders. The specialist's ability to identify small market orders and offer them better prices helps small traders.

Parlour and Seppi [15] use this insight to show that a hybrid market comprised of a limit order book and a specialist can coexist and even dominate a pure limit order book. The interest in this comparison stems from Glosten's [10] claim that the electronic open limit order book architecture is somehow "inevitable". Crucial to Glosten's results, however, are the assumptions of order flow anonymity and parity in terms of costs among liquidity providers, both of which need not hold in the case of the specialist.

While the answer to whether hybrid specialist markets can compete effectively against electronic limit order books could depend on specific trading arrangements and structural features, the most recent theoretical insight is that these two markets are more similar than different. Back and Baruch [3] allow traders to "work" the orders by splitting their demand and trading it over time in smaller increments. When traders behave in this fashion, the *ex post* pricing power of the specialist assumed in [15, 16] and [19] no longer gives the specialist an advantage. The reason is that even if the specialist can condition on the size of the arriving market order, he does not know whether it is part of a much larger order of an informed trader that is worked over time (i.e., he cannot condition on the size of the demand underlying the order). The specialist market structure therefore does not offer any general advantage over the pure limit order book.^a

It is still possible that the presence of a specialist would be more beneficial for a certain subset of the securities in the market. Grossman and Miller [11] model risk averse liquidity provision and examine the demand for dealer services that is created by investors' desire for immediacy of execution. They note that the specialist is far more important for the less active stocks. Profitable dealing does not arise endogenously in those stocks even in the absence of adverse selection considerations because the potential for profit is small relative to the fixed cost of maintaining a market presence (after taking into account the risk of holding an

inventory of these stocks). Sabourin [17] models the interaction of a limit order book and a designated market maker and shows that this hybrid structure offers more attractive prices than a pure limit order book for stocks with high fundamental volatility.

Specialists and Market Quality

The recent introduction of designated market makers to derivatives exchanges and stock markets around the world affords us the opportunity to empirically investigate the benefits of adopting the specialist market structure. Anand and Weaver [2] show that spreads declined significantly when the Chicago Board of Options Exchange (CBOE) introduced designated market makers in 1999. On the Chicago Board of Trade, the introduction of a designated market maker to the 10-year interest rate futures contract in 2002 resulted in increased volume, reduced transaction costs, and improved price efficiency [22]. Similarly, volume increased substantially and transaction costs declined when the Tel Aviv Stock Exchange introduced designated market makers to its thinly traded shekel-euro options in 2004 [8].

Several European stock exchanges implemented programs whereby less active stocks are given a choice of adding a designated market maker to accompany the auction market (usually a limit order book), effectively creating a hybrid specialist market structure. These initiatives appear to have resulted in significant improvement in market quality. For example, volume increased and spreads decreased after designated market makers were introduced on the Italian Stock Exchange [14]. Liquidity improved and either volatility or liquidity risk declined when such programs were instituted by the Stockholm Stock Exchange and Euronext [1] and [13]. Market quality also improved for Paris Bourse stocks traded in call auctions when designated market makers were employed [23].

The aforementioned research documented significant benefits in terms of market quality to having a specialist market structure for less actively traded stocks and derivatives contracts. A natural question is, therefore, how can specialists be compensated to ensure the provision of their services in these securities?

The Compensation of Specialists

Specialists are expected to lose from trading with better-informed investors. They also incur costs for keeping a market presence, and due to risk aversion would require an appropriate compensation for deviating from their optimal positions in risky securities. How do specialists make money? Investors' liquidity shocks generate price reversals in the market and create profitable trading opportunities for specialists in their capacity as dealers [11]. Beyond this mechanism, other opportunities for specialists critically depend on the rules that govern market interaction and specific devices instituted to compensate them.

For example, a significant source of revenue for NYSE specialists has been the fees earned from their brokerage function [20], but this part of their revenue has declined over the years. In some markets (e.g., the NYSE), specialists have the ability to better discern uninformed trading (if due to repeated interaction with brokers on the floor or through *ex post* pricing that allows conditioning on order size).^b In addition, designated market makers in certain markets (e.g., CBOE, NYSE) enjoy privileged access to information on the content of the limit order book, which enhances their ability to trade profitably.

Another mechanism used (e.g., on CBOE) to ensure profitability of dealing by designated market makers is to give them *pro rata* share of the order flow for execution even if they only match, rather than establish, the best prices in the market. For less active securities, however, Grossman and Miller [11] suggest that it may be impossible for specialists to make sufficient money by dealing to cover their costs. Markets have offered designated market makers reduced fees (to give them a cost advantage over other traders) or direct payments (see [8]) in exchange for a commitment to make markets continuously and provide quality quotes that satisfy minimum depth and maximum spread requirements.

Furthermore, if liquidity is priced (see **Liquidity Premium**), then the benefit of greater liquidity of a firm's stock would ultimately accrue to the firm in terms of lower cost of capital. As such, the firm should be willing to pay for the services of a designated market maker. This has been the model that was recently adopted by several European stock exchanges. At the center of the market architecture of these exchanges is a transparent electronic limit order book, and therefore the designated

market makers do not have *ex post* pricing ability, guaranteed order flow, or an informational advantage as to the content of the book. Being on the same footing as other traders who do not have an obligation to maintain continuous presence subject to minimum depth and maximum spread rules, the designated market makers can hardly be expected to make money (at least in less active stocks). Therefore, compensation arrangements include direct payments from the firm to the designated market makers, as well as indirect payments in the form of future business prospects like secondary offerings, banking services, or investor relations services [1, 13], and [23].

Conclusion

The hybrid structure of specialist markets combines the ability of investors to trade directly with other investors in an auction setting together with the presence of designated market makers. Empirical research documents improvements in market quality when less active securities move from a pure limit order book structure to a hybrid specialist structure.

Bessembinder *et al.* [5] claim that a designated market maker subject to a maximum spread rule can increase the allocational efficiency of prices because more investors would choose to trade when transactions costs are lower. In addition, [5] and [7] note that the informational efficiency of prices could be enhanced by the presence of a designated market maker. The reason is that obligations of the specialists to maintain price continuity or narrow spreads increase the profitability of informed trading and therefore more investors optimally choose to invest in gathering and analyzing information. As yet, an unanswered question is whether the societal benefits to investors outweigh the costs of compensating the specialists.

End Notes

^aGlosten [9] and Leach and Madhavan [12] model the specialist as a monopolist dealer without analyzing the hybrid market interaction between the specialist and the limit order book. Both papers show that a monopolist specialist market may be robust to informational asymmetries in that it can remain open when a market populated by competitive dealers would shut down.

^b See [4] for a model of how repeated interactions with floor brokers enable the specialists to offer investors better terms of trade.

Order Types

Most modern financial markets are *limit order markets* and use a continuous double-auction mechanism [5]. On these markets, investors can choose between different *order types* when they wish to buy or sell stocks. Each of them have specific characteristics that make them appropriate for certain types of investors or in certain situations.

The number of different order types supported on the different exchanges is actually quite large and brokers might also add complexity and propose yet more sophisticated order types to their customers. This article only reviews the most frequently used order types. As a conclusion, some empirical facts on order placement and the performance of market *versus* limit orders are highlighted.

Market Orders

The simplest order type is perhaps the *market order*: the investor chooses to buy or sell at the current best available price. As long as there are willing buyers and sellers, the order is guaranteed to be executed. An important property of a market order is that the investor only specifies which quantity he/she wants to trade, not at which price. Indeed, on fast-moving markets, he/she may well obtain an execution price that differs from the best price quoted at the moment he/she decided to send the order. It may also happen that he/she receives different prices for parts of the order, in particular for large orders.

Limit Orders

Unlike a market order, a *limit order* is an order to buy or sell at a specific price. A buy (sell) limit order can only be executed at the limit price or lower (higher). Thus, the investor has some control over the execution price that he/she will obtain, but the order might not be filled. One can distinguish two types of limit orders: limit orders that are submitted at or above the market price and those that are not. The first ones, sometimes called *marketable limit orders*, are immediately executed. Those of the second kind are stored in a queue called the *limit order book*. They

are executed if they are hit by market orders from the opposite side.

Stop Orders

A *stop order* is an example of a conditional order: a market order is sent once the price of a stock reaches a specified level. This type of order is used by investors who want to avoid big losses or protect profits without having to monitor the stock performance for an extended period of time. For instance, if an investor has a short position, he/she might decide to buy it back once his/her losses reach a threshold, that is, when the stock price exceeds a certain level. In the same way, he/she can limit his/her profits by buying the stocks when the price drops below a specified price. Stop orders might also be limit orders. In that case, a limit order is sent when the price reaches a level.

Hidden Orders and Iceberg Orders

Investors who wish to submit a large limit order might be concerned when their order gets noticed. A possibility is then to submit the *hidden order*. Such an order is not visible in the order book, but has usually lower time priority, that is, regular limit orders at the same price that are submitted later will be executed first. An *iceberg* (or *reserve*) order is similar except that it is not fully hidden: a fraction of the order size, called *peak volume*, is publicly disclosed. When the visible volume is filled and a hidden volume is still available, a new peak volume enters the book. On exchanges where iceberg orders are allowed, they can be quite frequent. For example, according to studies of iceberg orders on Euronext [1], 30% of the book volume is hidden.

Immediate or Cancel Orders

If a market participant wants to profit from a trading opportunity that he/she expects to last only a short period of time, he/she can consider sending a *immediate or cancel* order. This order either (partially) gets filled or is else cancelled. Thus, it never goes into the book and leaves no visible trace if it cannot be executed. This order type is similar to the *all or nothing* (sometimes called *fill or kill*) order. Orders of the

latter type must be completely executed or not at all. In this way, the investor avoids revealing his intention to trade if the entire quantity was not available.

Day Orders and Good 'Til Canceled Orders

An investor might want his/her order to expire if it is not executed. He/she can then submit a *day order*. Such an order is canceled if it is not executed on the day the order is placed. On the other hand, if he/she submits a good 'til canceled order (GTC), the order will remain active until the investor cancels it. Typically, his/her broker will, however, set a maximum time limit of 30–90 days after which the broker cancels the order.

Market-on-close Orders

A market-on-close (MOC) order is a market order that is submitted to execute as close to the closing price as possible. If a double-sided closing auction takes place at the end of the day (such as on the New York Stock Exchange (NYSE) or the Tokyo Stock Exchange), the order will participate in the auction. Investors might want to trade near the close because they expect liquidity to be high. Another reason might be that closing prices are widely used as a reference price (for instance, for the valuation of mutual fund shares or the determination of the payoffs to cash-settled derivatives [5]). An MOC order is then a way to obtain an execution price close to the reference price. There also exist *limit on close* orders, that is, limit orders submitted at the close. Finally, there are limit order that become market orders at the close (in Japan called *Funari* orders).

Reg NMS Order Types

In reaction to recent National Market System regulations (Reg NMS) promulgated by the United States Securities and Exchange Commission (SEC), several American exchanges developed new order types. In fact, according to Reg NMS brokers should respect the so-called Order Protection Rule, which states that one cannot ignore the top-of-book best bid and offers. This rule came into effect during the year

2007. Suppose that the best ask price for a given security is \$123.45 on Nasdaq, \$123.46 on the NYSE, and \$123.46 or more on the other market centers where it is quoted. The \$123.45 quote on Nasdaq is then protected and cannot be traded through, that is, if one sends a buy market order to the NYSE, the exchange has in principle to route it to Nasdaq. A new order type that is Reg.NMS compliant is a *do not ship* order, an order that is to be executed at one exchange. If the order would route to another market center, it will be cancelled. Another example is a Intermarket Sweep Order (ISO). This is a limit order designated to be executed exclusively at one market center. The sender fulfills the Reg NMS obligations by sending other orders to any market center quoting better prices. For more examples, see [9].

Peg Orders

With the competition between liquidity pools in the US and in Europe, some recently created venues such as Chi-X or BATS have introduced *peg orders*. These are orders that “follow” quotes from other exchanges (either the primary exchange or the best bid or offers). The venues thus hope to attract trading volume. For market participants, a peg order is convenient because they do not need to monitor the quotes on other exchanges and replace their order themselves if the price moves away. Also, alternative trading systems might be cheaper (lower exchange fees) and faster (lower latency).

Empirical Studies of Order Placement

The question of how investors submit their orders determines how the price is formed at the microstructure level. It has recently received much interest, triggered by the availability of huge datasets of order book data.

The probability that a limit order is sent at a price p has been shown to decay with the distance from the best price. However, the decay is slow, that is, algebraic [7]. It can be fitted by a Student distribution [6]. The distribution is symmetric, centered around the best price and the same for buying and selling. The probability that an order will be cancelled also decreases with its distance from the best

price. These findings have been observed across different markets such as the London Stock Exchange, Euronext, and Instinet and are expected to be to some degree “universal”. The distribution of the time to fill for executed limit orders and the time to cancel for canceled ones was studied in [2].

Performance of Market versus Limit Orders

The performance of the different order types is an issue of interest for both the practitioners and academic researchers. Although the cost of a market order can be considered to be half the bid-ask spread, the cost of a limit order is not unambiguously defined. In case the order is not executed because of adverse price movement, one should in some way add the cost of the missed opportunity. Moreover, if the order does get filled, it might have been hit by an investor with more information about the future price, a phenomenon that is called *adverse selection*.

In an early study, Harris and Hasbrouck [4] suggest that limit orders are performing better, even taking into account some penalty for nonexecuted orders. According to Handa *et al.* [3], the order-driven market is an ecological system with a competition between market and limit orders. This idea has been made more quantitative in [8], where it was suggested that on average limit orders and market orders have equal costs. Imposing that strategies that participate in a infinitesimal fraction of all market or limit orders have at best a marginal profit, one obtains a linear relation between bid-ask spread and the instantaneous impact of market orders, which is empirically verified. Thus, an investor who would try to earn from the spread by putting limit orders in the book would actually not

make money due to the impact of incoming market orders.

JULIEN KOCKELKOREN

Automated Trading

Technological change has revolutionized the way financial assets are traded. Investors place orders *via* computer rather than speaking to a broker on the phone. Trading floors have largely been replaced by electronic trading platforms [15]. The nature of order execution has changed dramatically as well, as many market participants now employ algorithmic trading (AT), commonly defined as the use of computer algorithms to manage the trading process. Starting from near zero in the 1990s, by 2007 AT was responsible for roughly one-third of trading volume in the United States and is expected to account for perhaps half of trading volume by 2010 [8]. The intense activity generated by algorithms threatens to overwhelm exchanges and market data providers [9], forcing significant upgrades to their infrastructures [8].

Before algorithmic trading, a pension fund manager wanting to buy 100 000 shares of IBM might have hired a broker-dealer to search for a counterparty to execute the entire quantity at once in a block trade. Alternatively, that institutional investor might have hired a broker to quietly “work” the order (possibly on the floor of the New York Stock Exchange), using his/her judgment and discretion to buy a little bit here and there over the course of the trading day to keep from driving the IBM share price up too far (see [16] for evidence of large orders being broken up). As trading became more electronic, it became easier and cheaper to replicate the human trader with a computer program doing algorithmic trading. Now virtually every large broker-dealer offers a suite of algorithms to its institutional customers to help them execute orders in a single stock, in pairs of stocks, or in baskets of stocks. Algorithms typically determine the timing, price, and quantity of orders, dynamically monitoring market conditions across different securities and trading venues, reducing market impact by optimally (and possibly randomly) breaking large orders into smaller pieces, and closely tracking benchmarks such as the volume-weighted average price (VWAP) over the execution interval.

Algorithms for Executing Large Orders

Execution of trades over a trading horizon involves complex dynamic optimization problems to determine order size, order frequency, and order type.

Bertsimas and Lo [3] study optimal execution strategies in the presence of temporary price impacts. Conditional on the constraint of completing the entire transaction by a fixed date, orders are broken into pieces so as to minimize cost. Almgren and Chriss [1] extend this by considering the risk that arises from breaking up orders and slowly executing them. In the basic Almgren and Chriss setup, the authors first assume an initial holding of $x_0 = X$ units of a security that must be completely liquidated before time T . Dividing T into N intervals of length $\tau = T/N$ and defining the discrete times $t_k = k\tau$, for $k = 0, \dots, N$, they solve for the optimal holdings, x_k , at each time t_k . Equivalently, this can be formulated as the series of trades to accomplish this liquidation, with $n_k = x_k - x_{k-1}$ being the number of units sold between times t_{k-1} and t_k . To capture the risk involved in the trading process (see [10] for the relationship between execution risk and investment risk), a price process for the security must be specified:

$$S_k = S_{k-1} + \sigma \tau^{1/2} \xi_k - \tau g\left(\frac{n_k}{\tau}\right) \quad (1)$$

for $k = 0; \dots, N$. Here σ represents the volatility of the asset, the ξ_k are draws from independent random variables each with zero mean and unit variance, and the permanent price impact of the trade, $g(v)$, is a function of the average rate of trading $v = n_k/\tau$ during the interval t_{k-1} and t_k . In addition, there may be a temporary price impact function, $h(v)$, which captures the temporary drop in average price per share caused by trading at average rate v during a time interval. Thus, the actual price per share received on sale k is

$$\tilde{S}_k = S_{k-1} - h\left(\frac{n_k}{\tau}\right) \quad (2)$$

where $h(v)$ does not impact the subsequent market price S_k . $g(v)$ and $h(v)$ can be chosen to reflect the trader’s beliefs about market dynamics and market microstructure.

By combining these and summing across periods, the proceeds of the liquidation are obtained:

$$\begin{aligned} \sum_{k=1}^N n_k \tilde{S}_k &= X S_0 + \sum_{k=1}^N \left(\sigma \tau^{1/2} \xi_k - \tau g\left(\frac{n_k}{\tau}\right) \right) x_k \\ &\quad - \sum_{k=1}^N n_k h\left(\frac{n_k}{\tau}\right) \end{aligned} \quad (3)$$

with the first term being the initial market value, the middle term including both the volatility and the permanent price impacts, and the final term being the temporary price impacts. Calculating the expected cost of trading, $C(x)$, as the difference between the initial value and the proceeds of the sales, we get

$$C(x) = \sum_{k=1}^N x_k g\left(\frac{n_k}{\tau}\right) + n_k h\left(\frac{n_k}{\tau}\right) \quad (4)$$

The variance of $C(x)$ is

$$V(C(x)) = \sigma^2 \tau \sum_{k=1}^N x_k^2 \quad (5)$$

Using this setup, Almgren and Chriss calculate the mean-variance efficient frontier for trading/liquidation strategies. Furthermore, assuming the objective is to minimize the function $C(x) - \lambda V(C(x))$, they calculate the optimal strategies for various values of λ . Almgren and Chriss show that as long as the parameters are fixed and known in advance, the optimal trading strategy can be calculated in advance and does not need to be updated dynamically. The calculation of such strategies may still be complex depending on the functional form of the permanent and transitory price impact functions $g(v)$ and $h(v)$. Some typical impact functions include power functions, weighted sums of linear and nonlinear functions, and exponential decay functions. The significant computer power often required to find the optimum under complex price impact functions makes implementation *via* algorithms attractive.

Numerous features have been added to the above model that significantly increase the complexity of the calculations and algorithms needed to find and implement the optimal trading strategies. Some of the most common enhancements include portfolio considerations and modeling the information that motivates the trade. Obizhaeva and Wang [20] optimize trading strategies assuming that liquidity does not replenish immediately after it is taken but only gradually over time. Algorithms can be improved by modeling variation within and across days to account for changing market conditions and predictable price movements [2]. Kissell and Malamut [17] discuss how trading should be sped up or slowed down conditional on traders' beliefs about whether past prices changes will mean reverting or continue. Many brokers build models with these considerations into their AT products that they sell to their clients.

The above optimal execution approaches either abstract away from the market mechanism or assume liquidity is taken *via* market orders. Implementation strategies that allow for more passive trading strategies enable the algorithm/trader to choose the type and aggressiveness of each order/component of the larger transaction. Cohen *et al.* [6] and Harris [13] focus on the simplest choice: market order *versus* limit order. If a trader chooses a nonmarketable limit order, the aggressiveness of the order is determined by its limit price [12] and [21]. How aggressively a limit order should be priced depends on how price affects the time to execution [19]. For assets that trade on multiple venues, determining where to send orders adds further complexity.

Market-making Algorithms

Many observers think of algorithms from the standpoint of institutional buy-side investor, but there are other important users of algorithms. Some hedge funds and broker-dealers supply liquidity using algorithms, competing with designated market-makers and other liquidity suppliers.

Most models take the traditional view that one set of traders provides liquidity *via* quotes or limit orders and another set of traders initiates a trade to take that liquidity—for either informational or liquidity/hedging motivations. Liquidity supply involves posting firm commitments to trade. These standing orders provide free trading options to other traders. Using standard option pricing techniques, Copeland and Galai [7] value the cost of the option granted by liquidity suppliers. The arrival of public information renders existing orders stale and can put the free trading option into the money. Biais *et al.* [4] provide a general theoretical framework for a liquidity supply price schedule $q_t(p)$ at time t :

$$\max_{q_t(p)} EU(C_t + I_t v_t + (v_t - p)q_t(p) | H_t) \quad (6)$$

where $U(x)$ is the utility function, C_t is the cash, I_t is the inventory of the security, v_t is the expected fundamental value, and H_t is the information set available. The use of algorithms in managing this price schedule (quotes) lowers the cost of monitoring changes in the information set due to changes in information and prices regarding that security or any related security. Any time an announcement,

trade, or quote change occurs in any security, a liquidity provider may want to revise their prices and quantities. Foucault *et al.* [11] study the equilibrium level of effort that liquidity suppliers should expend in monitoring the market to avoid this picking off risk. Improvements in technology allow algorithms to inexpensively perform such monitoring. In this way, AT may be a way to implement Black's [5] idea of limit orders indexed to a market index.

The widespread adoption of algorithms by traders supplying and demanding liquidity has led some observers to liken the situation to an arms' race [18]. While evidence points to algorithmic trading improving liquidity [14], the growing dominance of algorithms in trading makes their impact worthy of continued study.

Market Transparency

Market transparency is the degree to which information is widely available to market participants; this overview of transparency will be confined to the transparency of the market trading process without considering issues related to disclosure about the fundamentals of the securities that are traded.^a Given the importance of fleeting informational advantages in determining trading profits and losses, it is not surprising that transparency is and has been one of the most contentious issues in the design and regulation of trading systems. Financial economists' research—including theoretical modeling, experimental work, and empirical research—has also yielded a wide range of insights and results that provide a fairly ambivalent view of whether imposing transparency is desirable, or even feasible. There are conflicting interests between market participants along a variety of dimensions: informed or uninformed traders, liquidity-seeking (“buy-side”) *versus* liquidity-supplying (“sell-side”) agents, large *versus* small traders, broker-dealers *versus* agency brokers, as well as trading venues competing for transactions and listings. These gains and losses shape the trading and regulatory landscape.

The degree of transparency varies widely across instruments and markets. The United States market for major listed stocks is traditionally the most transparent. Since the 1975 amendments to the Securities Exchange Act, consolidated market information has been made available through designated exclusive securities information processors (SIP) that aggregate both quote information and trade reports. Over the years, the amount of information made available has been upgraded considerably.

At the other extreme lie the markets in thinly traded securities like municipal bonds, which are typically traded over the counter (OTC) by broker-dealers who fill most of their customers' orders in a principal capacity, and who trade among themselves in an interdealer market to manage their inventories. No firm prices are quoted, and information regarding the prices of completed trades is only made available for the most frequently traded issues, and that too only with a 1-day lag.

Market participants' information can include *pretrade* or quote transparency—the accurate real-time display of available price quotes, especially for

large-size trades, and of buying and selling interest in general—as well *posttrade* transparency or trade publication—a publicly available real-time record of the recent history of trades, including their time, size, price, location, and perhaps even the identities of the counterparties involved. We start by discussing research on each facet of transparency before touching on policy issues.

Pretrade or Quote Transparency

Most theoretical models argue that pretrade transparency benefits the buy side. Several mechanisms have been suggested.

Biais [9] considers a setting where market makers differ in their inventories (and thus in their reservation value for the security) but are otherwise taken to be approximately risk neutral and in agreement on the fundamental value of the security. He compares two market structures: (i) a transparent market in which dealer quotes can be observed by all market participants and (ii) an opaque market structure in which competing dealers have no information on the quotes of their peers. Effectively, the former is an English auction and the latter is a sealed-bid auction, and market makers' bidding strategies differ in the two settings. The “revenue equivalence theorem” of auction theory applies to this setting (risk-neutral bidders with independent, identically distributed private values) so that, as Biais concludes, the expected spread will be the same in both market structures. Beyond this stylized setting, textbook auction theory states that revenue equivalence breaks down if the bidders (the market makers) are truly risk averse, their private valuations are correlated or asymmetrically distributed, or there is an imperfectly known common value leading to a winner's curse problem [14]. In particular, within Biais's setting, de Frutos and Manzano [19] treat market-maker risk aversion without approximations and conclude that the opaque market is more liquid.

Yin [46] extends the analysis of Biais [9] by incorporating the idea that quote transparency exerts competitive pressure by eliminating customers' search costs, building on Diamond's [20] classic insight that search costs, no matter how small, can effectively destroy price competition and lead to monopoly pricing. Yin [46] considers the case in which customers

must pay a search cost in the opaque market, finding that the average bid–ask spread is smaller in the transparent market.

Evidence from the municipal bond market [28, 30, 43] illustrates the scope for rent extraction in an opaque setting. Municipal bond trading costs are substantially higher than those for equities, and particularly high for retail-sized trades relative to institutional trades, presumably because the investors are less-sophisticated negotiators. The Securities and Exchange Commission (SEC) report (2004) shows that for retail transactions (around \$10 000), an over-3% difference in the prices charged by different dealers filling orders within the same day is quite common (over 9% of transactions), even though normally intraday fluctuations in the fundamental value of the securities are zero or minimal; meanwhile, for large and more sophisticated institutional transactions (sized around \$1 million) a difference of over 1% is rare (0.4% of transactions) and a difference of over 2% absent in the sample.^b And although it is possible to verify *ex post* the prices of other transactions in a bond on the day of an order, investors rarely avail themselves of this opportunity to check up on their broker’s diligence and probity. Only the professional competence, energy, and sense of duty of the broker, limits the extent of price gouging. The underlying problem is that best execution has no teeth in a setting where individual securities are so thinly traded that it makes no sense for any market maker to spend the time and effort needed to quote continuous prices at which he/she is committed to trade. As a result, there is no firmly quoted, easily identifiable going market price. For more thickly traded securities, market makers are willing to quote prices anyway, because they see enough trading volume to recoup occasional losses to traders who hit stale quotes.

Interestingly, Biais and Green [10] show that the bond markets—both corporate and municipal—have not always been as opaque as they have been in the last decades. Their research shows that when bonds were centrally traded on the New York Stock Exchange (NYSE) in the early decades of the twentieth century, transaction costs for retail investors were substantially lower than they were on the OTC markets to which trading migrated after the 1940s.

A second mechanism whereby pretrade transparency can improve liquidity is analyzed by Pagano and Röell [38], who argue that in a centralized market

where all trading interest is exposed before transactions take place, liquidity providers are better able to gauge the extent of informed trading. This reduces the indirect transfer of informational rents (in the form of transaction costs induced by adverse selection) from uninformed to informed traders.

In early 1997, the SEC instituted new order-handling rules that further enhanced transparency; in particular, the “Limit Order Display Rule” that requires dealers to execute or display customers’ limit orders that improve upon their own (or send them on to a competitor), ensuring that best-priced limit orders are displayed to all market participants; and the “quote rule” requiring dealers who place quotes in multiple trading systems to make their best quotes available to the public. Both led to an immediate and substantial reduction in trading costs [2].

Hendershott and Jones [32] consider the impact of a 2002 regulatory enforcement action, which prompted the Island electronic communications network to suspend the display of the limit order book in its three most actively traded exchange traded funds (ETFs) for over a year. They find that quote display reduces trading costs and retains price discovery on Island, and that both transparency and reduced fragmentation play important roles in enhancing liquidity.

Baruch [3] argues that the introduction of an open limit order book on a monopoly specialist market such as the NYSE has the further advantage of reducing the informational advantage of the NYSE specialist over other liquidity providers. Leveling the playing field in this manner reduces the specialist’s participation rate and profits, and ensures better prices for immediacy demanders at the expense of the sell side. The evidence provided by Barclay *et al.* [2] and Boehmer *et al.* [13] agrees with this analysis, but Madhavan *et al.* [36] document that an earlier similar reform in Toronto led to reduced liquidity, though it did reduce specialist profit as predicted. They argue that too much transparency increases the “free option” cost of posting limit orders [18], leading to order withdrawal and a reduction in market depth, as well as diverting institutional trading volume away from the central market due to concerns about front running. However, more recently, Eom *et al.* [23] do find that pretrade transparency enhances liquidity on Korea’s electronic order-driven market, arguing that the Toronto findings may have been driven by endogeneity bias.

While desirable in theory, the amount of pretrade transparency that is achievable is limited to the extent that market participants are unwilling to publicly display firm quotes or limit orders, so that enforced limit order exposure may lead to a less deep limit order book. Many traders avail themselves of the opportunity to hide their intentions by posting large orders as “hidden orders” that are not publicly displayed in full; the hidden depth only shows up onscreen as and when the visible limit orders are knocked out by trading activity. The popularity of this strategy suggests that it may well substantially increase the depth of the limit order book; see [8] for a description of the use of hidden orders on Euronext Paris. The proliferation of “dark pools” of liquidity also points to the wish to keep trading interest at least to some extent out of the public eye, mitigating problems associated with front running and free options.

Posttrade Transparency

Promptly published information regarding the price, size, and perhaps even the identity of the counterparties involved in recent transactions provides an invaluable guide to market sentiment. Extending such information to all market participants would enable price quoters and limit order placers to compete more effectively, because they would not need to worry as much about the threat of being undercut by peers who have better information regarding recent trades. However, many practitioners have argued that this is not the case and that large traders, in particular, can obtain better prices if their trades are not published. When an order can be observed exclusively by the market maker who fills it, he/she can use the information conveyed by the order to make a profit on subsequent trading, and therefore his/her price quotes for the initial trade will be keener. In this respect, market makers have been likened to the bookmaker who declared himself happy to lose money to a particularly successful punter: “He’s my most valuable client. I always shorten the odds when he bets, and it saves me a fortune.”^c The basic idea was first modeled by Kyle [33] and Röell [41], who argue that under competitive market making, the overall net impact of posttrade opaqueness involves more favorable prices for informed traders and higher transaction costs for uninformed traders overall. Moreover, market makers who are not subjected to last trade publication can outcompete any

who are, so that with competition between multiple exchanges or between on- and off-exchange dealers, order flow is likely to gravitate to the least posttrade transparent setting. Madhavan [35] further shows that, because information-driven trades tend to be on the large side, large uninformed traders whose transactions are similar in size may benefit from opaqueness alongside informed traders, with retail uninformed investors bearing the full burden.

Experimental work by Bloomfield and O’Hara [11, 12] is consistent with these predictions, showing that competing dealers are willing to narrow their price quotes at the start of a trading game in an opaque market in order to capture order flow (though surprisingly, they do not fully recoup the initial losses at a later stage). Moreover, dealers who are not obliged to reveal their trades outcompete those who do have to, and dealers prefer to be nontransparent if given the choice.

Empirical evidence regarding the impact of posttrade transparency is mixed. Gemmill [26] does not discern a significant impact on liquidity from three different trade publication regimes (no publication, 90-min delayed publication and 24-h delayed publication) on the London Stock Exchange. This is surprising in light of the fact that throughout the period studied, London market makers steadfastly and vociferously campaigned against prompt last trade publication on the grounds that it would curtail their ability to offer attractive terms, particularly for wholesale trades. As Gemmill points out, they may have been more concerned with a potential loss of business to off-exchange dealers than with the equilibrium impact on market pricing that is the focus of the study.

Recent work on the institutional market for corporate bonds finds that improved posttrade transparency has led to a dramatic decline in execution costs. Starting in 2002, last trade publication through the TRACE system was phased in for the US investment-grade corporate bond market; and the reporting lag has been reduced over the years from 75 to 15 min. Studies by Bessembinder *et al.* [7], Edwards *et al.* [22], and Goldstein *et al.* [27] all conclude that trade publication led to significant declines in transaction costs. As in the municipal bond market, transaction costs are largest for retail-size trades, and the benefits of transparency have been most significant at the retail end. Moreover, the greater transparency has mitigated the informational advantage of the larger

dealers, reducing their market share. The studies estimate that the reduction in transaction costs as a result of TRACE represents roughly a \$1bn per year reduction in corporate bond dealers' market-making revenue. Bessembinder and Maxwell [6] report that, not surprisingly, many bond traders, analysts, brokers, and salesmen have seen substantial reductions in their earnings and exited the market. Post-TRACE, dealers conduct less fundamental analysis and are less willing to hold inventories, so that locating bonds involves more search over multiple intermediaries. On the positive side, TRACE seems to have facilitated the development of an electronic limit order market (Market Axess) in corporate bonds, and possibly contributed to the NYSE's ongoing initiative to upgrade its trading platform for bonds of listed companies.

If prompt trade publication is desirable, is it enforceable, and does it have unintended consequences? If reported trades are published quickly, market participants will find it in their interest to delay the reporting. Franks and Schaefer [25] point out that trade reporting deadlines can be evaded by the use of "protected trades": market makers informally offer a price to a customer for a large deal (with the understanding that they will, in practice, honor the commitment), but the deal is not officially finalized and confirmed until they have had time to unwind the resulting inventory. This delays the trade report—and its publication—beyond the regulators' intention. Moreover, it reduces immediacy and imposes some execution risk on large traders. Porter and Weaver [39] provide evidence that Nasdaq market makers indeed use late trade reporting to manage the flow of information: trades reported "out of sequence" (thus evading the 90s reporting deadline) are disproportionately large in size and much too common to be attributable to legitimate causes (such as computer glitches). An additional concern is that trading will migrate to venues that do not impose as much posttrade transparency. Many observers of the migration of the wholesale markets in European blue chip equities to London in the early 1990s have argued that the lack of trade publication on SEAQ International was a primary determinant. Europe-wide negotiations on market regulation and transparency have typically pitted the looser, more freewheeling regime of the London wholesale markets against the more centralized transparent regime prevailing in the home markets.

Optimal Transparency

Most studies focus on the effects of market transparency on market liquidity, informational efficiency, and the distribution of trading profits among market participants. Unless the general public's motivation for trading is fully articulated, explicit analysis of Pareto gains is ruled out. Some models do postulate that trading arises as a portfolio rebalancing response of risk-averse agents to random endowments, permitting some measure of analysis of deadweight gains and losses.

Cespa and Foucault [15] study how posttrade transparency affects allocative efficiency. Specifically, they consider a dynamic rational expectations model in the manner of Hellwig [31] in which only a fraction of investors observe transaction prices in real time. They show that it is never Pareto optimal to distribute information on past transaction prices to all investors: in their setting, risk sharing is more efficient when the market is not fully transparent. The reason is that dissemination of information thwarts risk sharing through the so-called Hirshleifer effect as well as intensifying competition among investors.

Anonymity

One aspect of transparency that has attracted considerable attention is the degree to which traders' (or at least their brokers') trading motivations and/or identities are revealed, either pre- or posttrade. The information that is potentially available goes beyond the size, direction, and price of quotes and order flow. We group a discussion of the treatment of such items of information here under the heading of anonymity.

Pretrade Anonymity

Most papers on anonymity focus on pretrade transparency. Some market structures, such as telephone dealership markets or floor markets, allow buy-side investors or their representatives to share information on their trading motives. Naturally, these market structures are nonanonymous. In general, nonanonymous pretrade communication among traders reduces adverse selection and improves liquidity.

For instance, Admati and Pfleiderer [1] show that if customers can "sunshine trade", that is, publicly

preannounce their intention to carry out a large transaction and convincingly establish that their trade is *not* based on superior information, they can improve the price at which they trade. Röell [42] shows that even if such information is conveyed exclusively to the uninformed customer's broker-dealer, at least some of the benefits remain, with the broker-dealer absorbing ("internalizing") roughly half the customer's order flow on own account. In both cases, the customer benefits, though as a result of the withdrawal of a part of the liquidity-driven order flow noise, the market at large becomes less liquid for other traders, namely, both information-based traders as well as those liquidity traders who are unable to certify their lack of information. Easley *et al.* [21] present evidence consistent with the idea that purchased order flow similarly involves cream skimming of order flow that is thought to be noninformation-driven; however, Battalio *et al.* [4] find no adverse impact on the liquidity of the main market when opportunities for internalization are introduced on competing regional exchanges, possibly due to intensified competition as order flow is drawn away.

The converse situation arises when informed traders show their hand. Chung *et al.* [16] consider the impact of the special arrangements whereby Swiss companies can publicly repurchase their own shares on a separate, nonanonymous "second trading line" platform. Price movements around the repurchases are consistent with the notion that share repurchases convey positive information, and the mechanism seems to have a positive impact on the liquidity of the main market, which can arguably be attributed to reduced asymmetries of information.

Benveniste *et al.* [5] emphasize another benefit of nonanonymous pretrade communication: it enables market makers and their clients to enter into long-term implicit contracts. In this way, market makers can incentivize their clients to disclose whether their trade is informed or not and adjust their quotes accordingly. Benveniste *et al.* go on to show that price discrimination between informed and uninformed investors is Pareto-improving.

Recent work considers the impact of transparency regarding the identities of agents on the sell side rather than the buy side.

In electronic limit order markets, the identities of liquidity suppliers can either be suppressed or disclosed to market participants. The effects of providing information about liquidity suppliers' identities are

analyzed by Foucault *et al.* [24] and Rindi [40]. Rindi assumes that limit orders are placed both by informed and uninformed agents, for instance, as in [29]. Disclosure of liquidity suppliers' identities enables market participants to observe informed traders' limit orders. The resulting reduction in the profitability of trading on information discourages the acquisition of information. Paradoxically this means that transparency can sometimes reduce liquidity because when fewer competing traders obtain information, risk averse liquidity suppliers, facing more uncertainty about the asset's value, are less willing to bid aggressively. Foucault *et al.* [24] consider a model in which limit order traders are differentially informed about future volatility. Better informed limit order traders can better control their exposure to the risk of being picked off and therefore earn larger expected profits. These rents, however, are limited as uninformed limit order traders draw inferences about the risk of being picked off from the bids placed in the limit order book. These inferences are noisier in an anonymous environment as limit order traders cannot tell whether quotes are set by informed traders or uninformed traders, leading to different bidding strategies by limit order traders in the anonymous and the nonanonymous market. Consequently, disclosing information about liquidity suppliers' identities should affect market liquidity and the informativeness of the limit order book about future volatility. In particular, this identifies conditions under which the anonymous market is more liquid.

Foucault *et al.* [24] provide empirical evidence consistent with these predictions, using data from Euronext Paris, where the limit order book became anonymous in 2001. They show that the switch to anonymity is associated with an increase in liquidity and a decrease in the informativeness of the limit order book about future volatility. Comerton-Forde *et al.* [17] conduct a similar empirical analysis for a larger sample of stocks listed on the Paris Bourse, the Tokyo Stock Exchange, and the Korea Stock Exchange. They also find that liquidity is larger in the anonymous environment for the three markets considered in their study.

An alternative hypothesis consistent with the evidence that pretrade sell-side anonymity enhances liquidity is proposed by Simaan *et al.* [44], who argue that disclosing liquidity suppliers' identities facilitates collusion. They find that dealers post more

aggressive quotes on electronic communication networks (ECNs) than on Nasdaq, as predicted by the collusion hypothesis.

Posttrade Anonymity

Naik *et al.* [37] consider a model with risk-averse market makers who, after first trading with a member of the public whose trade may have some information content, go on to rebalance the inventory on an interdealer market. They show that as long as market makers do not learn anything beyond the order size from their customer, a regime with prompt publication of the initial order yields a better price for the customer than in an opaque regime because there are no asymmetries of information to thwart optimal risk sharing at the second stage. However, if market makers are able to learn more from their customer than what is contained in the order size alone (in particular, if they learn what proportion of an order is information-driven) they will rebate information-driven order flow to such an extent that customers on average might prefer an opaque market without trade publication, because it offers better insurance against price risk.

Lastly, the identities of the parties to a transaction can be disclosed after a transaction. Waisburd [45] analyzes the effect of providing this type of information, using data from the Paris bourse. He considers a sample of stocks trading in two different regimes: one in which brokers' identities are revealed posttrade and one in which these identities are concealed. He finds that liquidity is lower in the posttrade anonymous regime. Interestingly, these results go in the opposite direction to those obtained for pretrade anonymity by Foucault *et al.* [24] or Comerton-Forde *et al.* [17]; thus, pretrade and posttrade anonymity have distinct effects.

Concluding Comments

Our survey has focused on transparency of the trading process, both in terms of quote display for prospective trades and publication of information regarding completed transactions. It is clear from the current crisis that transparency regarding the solvency of potential trading counterparties plays an important role in the functioning of markets during periods of high volatility. The pros and cons of central clearing

systems in providing collective insurance against counterparty risk is a topical but underanalyzed issue. The question of the pricing of transparency, and the costs of collecting and disseminating data, has also received more attention in the policy debate than in formal academic research.

Lastly, it should be clear that decisions regarding how much transparency is to be imposed are political. The beneficiaries of opaqueness tend to be large players such as bond dealers and banks. Such players have resisted the advent of transparent, centralized electronic trading in the bond markets, and they generally take ownership stakes in the competing platforms as a means of exerting influence. Active regulatory intervention may be needed to promote the interests of market participants who are not organized and influential.

End Notes

^aThere is a large and interesting literature about corporate disclosure (surveyed by Leuz and Wysocki [34]) and the complexity of security design.

^bCNNMoney.com (9/1/2004) reported that the NASD cracked down on major dealers who did not meet their obligation to buy and sell at fair prices. The discrepancies were major: one bond was sold on behalf of a customer for less than half the price that it traded for later in the day; another client received 70¢ on the dollar for a bundle of bonds with a fair value of 97¢.

Econometrics of Option Pricing

In 1997, Robert Merton and Myron Scholes were awarded the Nobel Memorial Prize in Economics “for a new method to determine the value of derivatives”. Of course, Fisher Black, who died two years earlier, had been associated with this huge contribution to financial engineering, now known as the *Black–Scholes* (BS) model. The purpose of econometrics of option pricing, as sketched later, is not really to check the empirical validity of this model. It has been widely documented that, by contrast with maintained assumptions of Black and Scholes geometric Brownian motion model, stock returns exhibit both stochastic volatility and jumps. Thus, the interesting issue is not the validity of the model itself. In this article, we focus on the assessment of the possible errors of the BS option pricing formula and on empirically successful strategies to alleviate them. We can get the right pricing and hedging formula with a wrong model. The widespread acceptance of the BS option pricing formula as a benchmark, among academics and investment professionals, is undoubtedly due to its usefulness for pricing and hedging options, irrespective of the unrealistic assumptions of the initial model. This is the reason the largest part of this article is focused on econometric modeling and inference about empirically valid extensions of the BS option pricing formula.

However, it is worth stressing the general econometric content of arbitrage pricing. As first emphasized by Cox *et al.* [20], the message of the BS approach goes beyond any particular specification of the underlying stochastic processes. Arbitrage-free pricing models generally allow to interpret derivative prices as expectations of discounted payoffs, when expectations are computed with respect to an equivalent martingale measure. In this respect, a nice correspondence between the theory of arbitrage pricing and econometrics is worth noting. While option contracts are useful to complete the markets and so to get a unique equivalent martingale measure. While only the historical probability distribution can be estimated from return data on the underlying asset, option prices data allow the econometrician to perform some statistical inference about the relevant martingale measure. Econometric approaches based

on implied volatility and also those used for option pricing that are unrelated to the lognormal benchmark of Black and Scholes, either because they are based on unrelated parametric models or because they introduce some nonparametric components, are discussed.

For sake of brevity, in this article, the only option contracts considered are European calls written on stocks. In the same manner, BS option pricing methodology has since been generalized to price many other derivative securities, and the econometric approaches sketched later can be extended accordingly.

The Information Content of Option Prices

Assume that all stochastic processes of interest are adapted in a filtered probability space $(\Omega, (\mathcal{F}_t), P)$. Under some regularity conditions, the absence of arbitrage is equivalent to the existence of an equivalent martingale measure Q (*see Equivalent Martingale Measures*). Without loss of generality, throughout we consider that the payoffs of options of interest are attainable [25]. Then, the arbitrage-free price of these options is defined, without ambiguity, as expectation under the probability measure Q of the discounted value of their payoff. Moreover, for a European call with maturity T , we characterize its arbitrage price at time $t < T$ as the discounted value at time t of its expectation under the time t forward measure $Q_{t,T}$ for time T . By Bayes rule, $Q_{t,T}$ is straightforwardly defined as equivalent to the restriction of Q on $\mathcal{F}_T$. The density function $dQ_{t,T}/dQ$ is $[B(t, T)]^{-1}(B_t/B_T)$, where B_t denotes the value at time t of a bank account, while $B(t, T)$ is the time t price of a pure discount bond (with unit face value) maturing at time T . If K and S_t denote, respectively, the strike price and the price at time t of the underlying stock, the option price C_t at time t is

$$C_t = B(t, T)E^{Q_{t,T}}\text{Max}[0, S_T - K] \quad (1)$$

Such a formula (1) provides a decomposition of the option price into two components:

$$C_t = S_t \Delta_{1t} - K \Delta_{2t} \quad (2)$$

where

$$\Delta_{2t} = B(t, T)Q_{t,T}[S_T \geq K] \quad (3)$$

and

$$\Delta_{1t} = \Delta_{2t}E^{Q_{t,T}}\left[\frac{S_T}{S_t} \mid S_T \geq K\right] \quad (4)$$

It immediately follows (see [34], pp. 140, 169) that

$$\Delta_{2t} = -\frac{\partial C_t}{\partial K} \quad (5)$$

In other words, a cross section at time t of European call option prices, all maturing at time T but with different strike prices K , provides information about the pricing probability measure $Q_{t,T}$. In the limit, a continuous observation of the function $K \longrightarrow C_t$ (or of its partial derivative $\partial C_t / \partial K$) would completely characterize the cumulative distribution function of the underlying asset return (S_T / S_t) under $Q_{t,T}$. Let us rather consider it through the probability distribution of the continuously compounded net return on the period $[t, T]$:

$$r_S(t, T) = \log \left[\frac{S_T B(t, T)}{S_t} \right] \quad (6)$$

With (log-forward) moneyness of the option measured by

$$x_t = \log \left[\frac{K B(t, T)}{S_t} \right] \quad (7)$$

the probability distribution under $Q_{t,T}$ of the net return on the stock $r_S(t, T)$ is characterized by its survival function deduced from equations (3) and (5) as

$$G_{t,T}(x_t) = -\exp(-x_t) \frac{\partial C_t}{\partial x_t} \quad (8)$$

where

$$\begin{aligned} C_t(x_t) &= \frac{C_t}{S_t} \\ &= E^{Q_{t,T}} \{ \text{Max}[0, \exp(r_S(t, T)) - \exp(x_t)] \} \end{aligned} \quad (9)$$

For the purpose of easy assessment of suitably normalized orders of magnitude, practitioners often prefer to plot the BS-implied volatility $\sigma_{t,T}^{\text{imp}}(x_t)$ rather than the option price $C_t(x_t)$ itself, as a function of moneyness x_t . The key reason that makes this sensible is that, in the BS model, the pricing distribution is indexed by a single volatility parameter σ . Under BS' assumptions, the probability distribution of the net return $r_S(t, T)$ under $Q_{t,T}$ is the normal one with mean $(-1/2)(T - t)\sigma^2$ and variance $(T - t)\sigma^2$. This distribution is denoted by $\aleph_{t,T}(\sigma)$.

Then, the BS-implied volatility $\sigma_{t,T}^{\text{imp}}(x_t)$ is defined as the value of the volatility parameter σ^2 that would generate the observed option price $C(x_t)$ as if the

distribution of net return under $Q_{t,T}$ was the normal $\aleph_{t,T}(\sigma)$. In other words, $\sigma_{t,T}^{\text{imp}}(x_t)$ is characterized as the solution of the following equation:

$$C_t(x_t) = BS_h[x_t, \sigma_h^{\text{imp}}(x_t)] \quad (10)$$

where $h = T - t$ and

$$BS_h[x, \sigma] = N[d_1(x, \sigma, h)] - \exp(x)N[d_2(x, \sigma, h)] \quad (11)$$

where N is the cumulative distribution function of the standardized normal distribution and

$$d_1(x, \sigma, h) = \frac{-x}{\sigma\sqrt{h}} + \frac{1}{2}h\sigma^2 \quad (12)$$

$$d_2(x, \sigma, h) = \frac{-x}{\sigma\sqrt{h}} - \frac{1}{2}h\sigma^2 \quad (13)$$

It is worth recalling that the common use of the BS-implied volatility $\sigma_h^{\text{imp}}(x_t)$ by no means implies that the BS model is thought as a well-specified one. By equation (10), $\sigma_h^{\text{imp}}(x_t)$ is nothing but a known strictly increasing function of the observed option price $C_t(x_t)$. When plotting the volatility smile as a function $x_t \longrightarrow \sigma_h^{\text{imp}}(x_t)$ rather than $x_t \longrightarrow C_t(x_t)$, a convenient rescaling of the characterization (8) of the pricing distribution is simply considered. However, this rescaling depends on x_t and, by definition, produces a flat volatility smile whenever the BS pricing formula is valid in the cross section (for all moneyness levels at a given maturity) for some specific value of the volatility parameter. Note that for this the validity of the BS model itself is only a sufficient but not a necessary condition.

How to Graph the Smile

When the volatility smile is not flat, its pattern obviously depends on whether implied volatility $\sigma_h^{\text{imp}}(x_t)$ is plotted against strike K , moneyness (K/S_t) , forward moneyness $(KB(t, T)/S_t) = \exp(x_t)$, log-forward moneyness x_t , and so on. The optimal choice of variable depends on what kind of information is expected to be revealed immediately on plotting implied volatilities. The common terminology *volatility smile* suggests that initially it was thought of as a kind of U-shaped pattern, whereas more recent words such as *smirk* or *frown* suggest that the focus is set on frequently observed asymmetries with respect to

a symmetric benchmark. Even more explicitly, since the volatility smile is supposed to reveal the underlying pricing probability measure $Q_{t,T}$, a common belief is that asymmetries observed in the volatility smile reveal a corresponding skewness in the distribution of (log) return under $Q_{t,T}$. Note, in particular, that, as mentioned above, a flat volatility smile at level σ characterizes a normal distribution with mean $(-\sigma^2/2)$ and variance σ^2 .

Beyond the flat case, the common belief of a close connection between smile asymmetries and risk-neutral skewness requires further qualification. First, the choice of variable must of course matter for discussion of smile asymmetries. We argue later that log-forward moneyness x_t is the right choice, that is, the fact that the smile asymmetry issue must be understood as a violation of the identity:

$$\sigma_h^{\text{imp}}(x_t) = \sigma_h^{\text{imp}}(-x_t) \quad (14)$$

This identity is actually necessary and sufficient to deduce from equation (10) that the general option pricing formula (9) fulfills the same kind of symmetry property as the BS one:

$$C_t(x) = 1 - \exp(x) + \exp(x)C_t(-x) \quad (15)$$

Although equation (15) is automatically satisfied when $C_t(x) = BS_h[x, \sigma]$ (by the symmetry property of the normal distribution: $N(-d) = 1 - N(d)$), it characterizes the symmetry property of the forward measure that corresponds to volatility smile symmetry. It actually mimics the symmetry property of the normal distribution with mean $(-\sigma^2/2)$ and variance σ^2 , which would prevail in the case of validity of the BS model. By differentiation of equation (15) and comparison with equation (8), the following can be easily checked:

The volatility smile is symmetric in the sense of equation (14) if and only if, when $f_{t,T}$ stands for the probability density function of the log-return $r_S(t, T)$ under the forward measure $Q_{t,T}$, $\exp(x/2) f_{t,T}(x)$ is an even function of x .

In conclusion, the relevant concept of symmetry amounts to considering pairs of moneynesses that are symmetric to each other in the following sense:

$$x_{1t} = \log \left[\frac{K_1 B(t, T)}{S_t} \right] = -x_{2t} = \log \left[\frac{S_t}{K_2 B(t, T)} \right] \quad (16)$$

In other words, the geometric mean of the two strike prices coincides with the current stock price:

$$\sqrt{K_1 B(t, T)} \sqrt{K_2 B(t, T)} = S_t \quad (17)$$

To conclude, it is worth noting that graphing the smile as a function of the log-moneyness x_t is even more relevant when one maintains the natural assumption that option prices are homogeneous functions of degree one with respect to the pair (S_t, K) . Merton [39] advocated this homogeneity property to preclude any “perverse local concavity” of the option price with respect to the stock price. It is obvious from equation (9) that a sufficient condition for homogeneity is that, as in the BS case, the pricing probability distribution $Q_{t,T}$ does not depend on the level S_t of the stock price. This is the reason, as discussed by Garcia and Renault [30], homogeneity holds with standard stochastic volatility option pricing models and does not hold for GARCH option pricing.

For our purpose, the big advantage of the homogeneity assumption is that it allows to compare volatility smiles (for a given time to maturity) at different dates since then the implied volatility $\sigma_h^{\text{imp}}(x_t)$ depends only on moneyness x_t and not directly on the level S_t of the underlying stock price. Moreover, from the Euler characterization of homogeneity,

$$C_t = S_t \frac{\partial C_t}{\partial S_t} + K \frac{\partial C_t}{\partial K} \quad (18)$$

we deduce (by comparing equations 2 and 5) that

$$\Delta_{1t} = \frac{\partial C_t}{\partial S_t} \quad (19)$$

is the standard delta-hedging ratio. Note that a common practice is to compute a proxy of Δ_{1t} by plugging $\sigma_h^{\text{imp}}(x_t)$ in the BS delta ratio. Unfortunately, according to some probability distribution of the volatility parameter, this approximation suffers from a convexity bias when the correct option price is a mixture of BS prices (see below). Renault [42] showed that the BS delta ratio (computed with $\sigma_h^{\text{imp}}(x_t)$) underestimates (respectively, overestimates) the correct ratio Δ_{1t} when the option is in the money (respectively, out of the money), that is, when $x_t < 0$ (respectively, $x_t > 0$).

Implied Risk Aversion

Under suitable assumptions for preferences and endowment shocks, it is well known that market completeness allows us to introduce a representative investor with a utility function U . Assuming that he/she can consume at date t and at the fixed future date T and that he/she receives one share of the stock as endowment at date t , the representative investor adjusts the dollar amount invested in the stock at each intermediary date in order to maximize the expected utility of his/her terminal consumption at time T (*see Expected Utility Maximization*). In equilibrium, the investor optimally invests all his/her wealth in the risky stock and then consumes the terminal value S_T of the stock. Thus, the Euler first-order condition for optimality imposes that the price π_t at time t of any contingent claim that delivers the dollar amount g_T at time t is such that

$$\pi_t = E^P \left[\beta^{T-t} \frac{U'(S_T)}{U'(S_t)} g_T \mid \mathcal{F}_t \right] \quad (20)$$

where $E^P [\cdot \mid \mathcal{F}_t]$ denotes the conditional expectation given $\mathcal{F}_t$ with respect to the historical probability measure P . β is the subjective discount factor. By identifying equation (20) with equation (1), we deduce that the density function given $\mathcal{F}_t$ of $Q_{t,T}$ with respect to P is proportional to $U'(S_T)$. Thus, if f_t^* (respectively, f_t) stands for the density function given $\mathcal{F}_t$ of the distribution function of S_T under the martingale measure Q (respectively under the historical measure P), we have (f_t^*/f_t) proportional to the marginal utility function and thus, by logarithmic derivatives,

$$\rho_t(S_T) = -S_T \frac{U''(S_T)}{U'(S_T)} = S_T \left(\frac{f_t'(S_T)}{f_t(S_T)} - \frac{f_t^{*'}(S_T)}{f_t^*(S_T)} \right) \quad (21)$$

where $\rho_t(S_T)$ is, by definition, the Arrow–Pratt measure of relative **risk aversion**. Note that the result would not have changed if we had used the forward probability measure $Q_{t,T}$ (*see Forward and Swap Measures*) instead of the risk-neutral one Q . Since as explained in the first section, the observation at time t of a cross section of option prices written on S_T allows us to infer these probability measures, it suggests that risk-aversion functions or preference parameters may be extracted from observed option

prices. Aït-Sahalia and Lo [4] and Jackwerth [35] proposed nonparametric approaches to recover risk-aversion functions across wealth states from observed stock and option prices. Bliss and Panigirtzoglou [10], Garcia *et al.* [29], and Rosenberg and Engle [45] have estimated preference parameters based on parametric asset pricing models with several specifications of the utility function.

These efforts to exploit prices of options to recover fundamental economic parameters have produced puzzling results. Aït-Sahalia and Lo [4] found that the nonparametrically implied function of relative risk aversion varies significantly across the range of S&P 500 index values, from 1 to 60, and is U-shaped. Jackwerth [35] also found that the implied absolute risk-aversion function is U-shaped around the current forward price and also that it can become negative. Parametric empirical estimates of the coefficient of relative risk aversion also show considerable variation. Rosenberg and Engle [45] reported values ranging from 2.36 to 12.55 for a power utility pricing kernel across time, while Bliss and Panigirtzoglou [10] estimated average values between 2.33 and 11.14 for the same S&P 500 index for several option maturities. Garcia *et al.* [29] estimated a consumption-based asset pricing model with regime-switching fundamentals and Epstein and Zin [23], the preferences. The estimated parameters for risk aversion and intertemporal substitution are reasonable, with average values of 0.6838 and 0.8532, respectively, over the period 1991–1995.

The general conclusion is that empirical risk-neutral distributions that are computed without a precise account of the state variables that enter into the investors' information sets cannot provide valuable insights on intertemporal preferences. For example, Chabi-Yo *et al.* [17] showed that in an economy with regime changes either in fundamentals or in preferences, an application of the nonparametric methodology used by Jackwerth [35] to recover risk aversion will lead to similar negative estimates of the risk-aversion function in some states of wealth even though the risk-aversion functions are consistent with economic theory within each regime.

Implied Volatility as a Calibrated Parameter

Formula (20) puts forward the so-called pricing kernel $m_{t,T} = \beta^{T-t} \frac{U'(S_T)}{U'(S_t)}$ that emphasizes the role of

risk aversion. In particular, in the case of constant relative risk aversion ($\rho_t(S_T) = -S_T \frac{U''(S_T)}{U'(S_T)} = a > 0$), the log-pricing kernel is perfectly correlated to the log-return on the stock:

$$\text{Log}(m_{t,T}) = -a \text{Log} \left[\frac{S_T}{S_t} \right] + (T - t) \text{Log}(\beta) \quad (22)$$

More generally, it is convenient to rewrite the call-pricing equation (1) in terms of the pricing kernel:

$$C_t = E^P [m_{t,T} \text{Max}[0, S_T - K] | \mathcal{F}_t] \quad (23)$$

where the general definition of the pricing kernel (*see also Pricing Kernels*) gives

$$\frac{dQ_{t,T}}{dP} = \frac{m_{t,T}}{B(t, T)} \quad (24)$$

It is easy to check that the general call-pricing formula (23) collapses into the BS one when the two following conditions are fulfilled:

1. The conditional distribution given $\mathcal{F}_t$ of the log-return $\text{Log} \left[\frac{S_T}{S_t} \right]$ is normal with constant variance σ .
2. The log-pricing kernel $\text{Log}(m_{t,T})$ is perfectly correlated to the log-return on the stock as in equation (22).

We get the first interesting generalization of the BS formula by now considering that the log-return $\text{Log} \left[\frac{S_T}{S_t} \right]$ and the log-pricing kernel $\text{Log}(m_{t,T})$ may be jointly normally distributed given $\mathcal{F}_t$, with conditional moments possibly depending on the conditional information at time t . Interestingly enough, it can be shown that the call price computed from formula (23) with this joint conditional lognormal distribution will explicitly depend on the conditional moments only through the conditional stock volatility:

$$(T - t) \sigma_{t,T}^2 = \text{Var} \left[\text{Log} \left[\frac{S_T}{S_t} \right] | \mathcal{F}_t \right] \quad (25)$$

More precisely, we get the following option pricing formula:

$$C_t = S_t B_{S_{T-t}}[x_t, \sigma_{t,T-t}] \quad (26)$$

Formula (26) is actually the generalization of the “risk-neutral valuation relationship” (RNVR) put forward by Brennan [12]. With joint log-normality

of return and pricing kernel, we find again the BS functional form due to the Cameron–Martin formula (a static version of Girsanov’s theorem), which tells us that when X and Y are jointly normal,

$$E \{ \exp(X) g(Y) \} = E[\exp(X)] E \{ g[Y + \text{cov}(X, Y)] \} \quad (27)$$

While the term $E[\exp(X)]$ will give $B(t, T)$ (with $X = \text{Log}(m_{t,T})$), the term $\text{cov}(X, Y)$ (with $Y = \text{Log} \left[\frac{S_T}{S_t} \right]$) will make the risk-neutralization since $E \{ \exp(X) \exp(Y) \} = E[\exp(X)] E \{ \exp[Y + \text{cov}(X, Y)] \}$ must be 1.

From an econometric viewpoint, the interest of equation (26), when compared to equation (10), is to deliver a flat volatility smile but with an implied volatility level that may be time varying and correspond to the conditional variance of the conditionally lognormal stock return. In other words, the time-varying volatility of the stock becomes observable as calibrated from option prices:

$$\sigma_{t,T} = \sigma_{T-t}^{\text{imp}}(x_t) \quad \forall x_t \quad (28)$$

The weakness of this approach is its lack of robustness with respect to temporal aggregation. In the GARCH-type literature, stock returns may be conditionally lognormal when they are considered on the elementary period of the discrete-time setting ($T = t + 1$) while implied time-aggregated dynamics are more complicated. This is the reason the GARCH option pricing literature [21, 33]) maintains formula (26) only for $T = t + 1$. Nonflat volatility smiles may be observed with longer times to maturity. Kallsen and Taqqu [37] provided a continuous-time interpretation of such GARCH option pricing.

Implied Volatility as an Expected Average Volatility

To account for excess kurtosis and skewness in stock log-returns, a fast empirical approach amounts to considering that the option price at time t is given by a weighted average:

$$\alpha_t S_t B_{S_h}[x_t, \sigma_{1t}] + (1 - \alpha_t) S_t B_{S_h}[x_t, \sigma_{2t}] \quad (29)$$

The rationale for equation (29) is to consider that a mixture of two normal distributions with standard

errors σ_{1t} and σ_{2t} and weights α_t and $(1 - \alpha_t)$, respectively, may account for both skewness and excess kurtosis in stock log-return. The problem with this naive approach is that it does not take into account any risk premium associated with the mixture component. More precisely, if we want to accommodate a mixture of normal distributions with a mixing variable $U_{t,T}$, we can rewrite equation (23) as

$$C_t = E^P \left\{ E^P [m_{t,T} \text{Max}[0, S_T - K] \mid \mathcal{F}_t, U_{t,T}] \mid \mathcal{F}_t \right\} \quad (30)$$

where, for each possible value $u_{t,T}$ of $U_{t,T}$, a BS formula such as equation (26) is valid for computing

$$E^P [m_{t,T} \text{Max}[0, S_T - K] \mid \mathcal{F}_t, U_{t,T} = u_{t,T}] \quad (31)$$

In other words, it is true that, as in equation (29), the conditional expectation operator (given $\mathcal{F}_t$) in equation (30) displays the option price as a weighted average of different BS prices with the weights corresponding to the probabilities of the possible values $u_{t,T}$ of the mixing variable $U_{t,T}$. However, the naive approach (29) is applied incorrectly if we do not take into account the fact that the additional conditioning information $U_{t,T}$ should lead to modify some key inputs in the BS option pricing formula. Suppose that investors are told that the mixing variable $U_{t,T}$ will take the value $u_{t,T}$, then the current stock price would no longer be

$$S_t = E^P [m_{t,T} S_T \mid \mathcal{F}_t] \quad (32)$$

but

$$S_t^*(u_{t,T}) = E^P [m_{t,T} S_T \mid \mathcal{F}_t, U_{t,T} = u_{t,T}] \quad (33)$$

For the same reason, the pure discount bond that delivers \$1 at time T will no longer be priced at time t as

$$B(t, T) = E^P [m_{t,T} \mid \mathcal{F}_t] \quad (34)$$

but as

$$B^*(t, T)(u_{t,T}) = E^P [m_{t,T} \mid \mathcal{F}_t, U_{t,T} = u_{t,T}] \quad (35)$$

In other words, various BS option prices that are averaged in a mixture approach such as equation (29) must be computed, not with actual values $B(t, T)$ and S_t of the current bond and stock prices, but with values $B^*(t, T)(u_{t,T})$ and $S_t^*(u_{t,T})$ not directly

observed but computed from equations (35) and (33). In particular, the key inputs, underlying stock price and interest rate, should be different in various applications of the BS formulas like $BS_h[x, \sigma_1]$ and $BS_h[x, \sigma_2]$ in equation (29). This remark is crucial for the conditional Monte Carlo approach, as developed, for instance, by Willard [47] in the context of option pricing with stochastic volatility. Revisiting a formula initially derived by Romano and Touzi [44], Willard [47] noted that the variance reduction technique, known as *conditional Monte Carlo*, can be applied even when the conditioning factor (the stochastic volatility process) is instantaneously correlated with the stock return as it is the case when leverage effect is present. He stressed that “by conditioning on the entire path of the noise element in the volatility (instead of just the average volatility), we can still write the option’s price as an expectation over Black–Scholes prices by appropriately adjusting the arguments to the Black–Scholes formula”. Willard’s [47] “appropriate adjustment” of the stock price is actually akin to equation (33). Moreover, he does not explicitly adjust the interest rate according to equation (35) and works with a fixed risk-neutral distribution. More generally, the continuous-time dynamics of a pricing kernel $m_{t,T}$ is considered, which is seen as the relative increment of a pricing kernel process M_t :

$$m_{t,T} = \frac{M_T}{M_t} \quad (36)$$

The key idea of the mixture model is then to define a conditioning variable $U_{t,T}$ such that the pricing kernel process and the stock price process jointly follow a bivariate geometric Brownian motion under the conditional probability distribution given $U_{t,T}$. The mixing variable $U_{t,T}$ will typically show up as a function of a state variable path $(X_\tau)_{t \leq \tau \leq T}$. More precisely, we specify the jump-diffusion model:

$$\begin{aligned} d(\log S_t) &= \mu(X_t) dt + \alpha(X_t) dW_{1t} \\ &\quad + \beta(X_t) dW_{2t} + \gamma_t dN_t \end{aligned} \quad (37)$$

$$\begin{aligned} d(\log M_t) &= h(X_t) dt + a(X_t) dW_{1t} \\ &\quad + b(X_t) dW_{2t} + c_t dN_t \end{aligned} \quad (38)$$

where (W_{1t}, W_{2t}) is a two-dimensional standard Brownian motion, N_t is a Poisson process with intensity $\lambda(X_t)$ depending on the state variable X_t . Given

the jump dates, the jump amplitudes at these dates are independent draws (γ_t, c_t) in a fixed bivariate normal distribution. These draws are also independent of the state variable process X . The Brownian motion W_1 is assumed to be part of the state variable vector X to capture the possible instantaneous correlation between ex-jump volatility of the stock (as measured by $V_t = \alpha^2(X_t) + \beta^2(X_t)$) and its Brownian innovation. More precisely, the correlation coefficient $\rho(X_t) = \frac{\alpha(X_t)}{\sqrt{V_t}}$ measures the so-called leverage effect.

The jump-diffusion model (37 and 38) is devised such that, given the state variables path $(X_\tau)_{t \leq \tau \leq T}$ as well as the number $(N_T - N_t)$ of jumps between times t and T , the joint normality of $(\log S_T, \log m_{t,T})$ is maintained. This allows us to derive a generalized Black and Scholes (GBS) option pricing formula by application of equations (30) and (26):

$$C_t = S_t E^P[\xi_{t,T} B S_{T-t}(x_t^*, \sigma_{t,T}) | \mathcal{F}_t] \quad (39)$$

where

$$\sigma_{t,T}^2 = \int_t^T [1 - \rho^2(X_\tau)] V_\tau d\tau + (N_T - N_t) \text{Var}(\gamma_t) \quad (40)$$

and

$$x_t^* = \log \left[\frac{K B^*(t, T)}{S_t \xi_{t,T}} \right] \quad (41)$$

where $S_t \xi_{t,T}$ and $B^*(t, T)$ correspond to $S_t^*(u_{t,T})$ and $B^*(t, T)(u_{t,T})$, respectively, which are defined in equations (33) and (35). General computations of these quantities in the context of a jump-diffusion model can be found in [27] and [48]. Let us exemplify these formulas when there is no jump. Then, we can define a short-term interest rate as

$$r(X_t) = -h(X_t) - \frac{1}{2}[a^2(X_t) + b^2(X_t)] \quad (42)$$

and then

$$\begin{aligned} B^*(t, T) = & \exp \left[- \int_t^T r(X_\tau) d\tau \right] \\ & \times \exp \left[\int_t^T a(X_\tau) dW_{1\tau} - \frac{1}{2} \int_t^T a^2(X_\tau) d\tau \right] \end{aligned} \quad (43)$$

and

$$\begin{aligned} \xi_{t,T} = & \exp \left[\int_t^T [a(X_\tau) + \alpha(X_\tau)] dW_{1\tau} \right. \\ & \left. - \frac{1}{2} \int_t^T [a(X_\tau) + \alpha(X_\tau)]^2 d\tau \right] \end{aligned} \quad (44)$$

In particular, it can be easily checked that

$$B(t, T) = E^P[B^*(t, T) | \mathcal{F}_t] \quad (45)$$

and

$$S_t = E^P[S_t \xi_{t,T} | \mathcal{F}_t] \quad (46)$$

For now, the difference between $S_t \xi_{t,T}$ and $B^*(t, T)$ and their respective expectations S_t and $B(t, T)$ are neglected. It is then clear that the GBS formula warrants the interpretation of the BS-implied volatility $\sigma_{T-t}^{\text{imp}}(x_t)$ as approximatively an expected average volatility. Neglecting convexity effects (non-linearity of the BS formula with respect to volatility), the GBS formula would actually give

$$[\sigma_{T-t}^{\text{imp}}(x_t)]^2 = E^P[\sigma_{t,T}^2 | \mathcal{F}_t] \quad (47)$$

The likely impact of the difference between $S_t \xi_{t,T}$ and $B^*(t, T)$ and their respective expectations S_t and $B(t, T)$ is twofold. First, a nonzero function $a(X_\tau)$ must be understood as a risk premium on the volatility risk. In other words, the above interpretation of $\sigma_{T-t}^{\text{imp}}(x_t)$ as approximatively an expected average volatility can be maintained by using risk-neutral expectations. Considering the BS-implied volatility as a predictor of volatility over the lifetime of the option is tantamount to neglecting the volatility risk premium. Beyond this risk premium effect, the leverage effect $\rho(X_t)$ will distort this interpretation through its joint impact on $\sigma_{t,T}^2$ and also on $\xi_{t,T}$ (through $\alpha(X_t) = \rho(X_t)\sqrt{V_t}$). Although Renault and Touzi [43] have shown that we will get a symmetric volatility smile in the case of zero-leverage, Renault [42] explained that, with nonzero leverage, the implied distortion of the stock price by the factor $\xi_{t,T}$ will produce asymmetric volatility smirks. More precisely, Yoon [48] characterized the cumulative impact of the two effects of leverage and showed that they compensate each other almost exactly for at the money options. Finally, Comte and Renault's [18] long-memory volatility model explains that, in spite of the time averaging in equations (40) and (47), the

volatility smile does not become flat even for long-term options.

The close connection (equations 40 and 47) between BS-implied volatility and the underlying volatility process ($\sqrt{V_t}$) has inspired a strand of literature on estimating volatility dynamics from option prices data. Pastorello *et al.* [41] consider directly $[\sigma_{T-t}^{\text{imp}}(x_t)]^2$ as a proxy for squared spot volatility V_t and correct the resulting approximation bias in estimating volatility dynamics by indirect inference. The “implied-states approach” (see [40] and references therein) more efficiently uses the exact relationship between $\sigma_{T-t}^{\text{imp}}(x_t)$ and V_t , as given by equations (40) and (47) for a given spot volatility model, to estimate the volatility parameters by maximum likelihood or generalized method of moments. Finally, Garcia *et al.* [28] simplified the procedure by taking advantage of high-frequency intraday return data for a direct measurement of the integrated volatility $\int_t^T V_\tau d\tau$.

Data-driven Approaches

In this section, we discuss methods that are, to various degrees, data-driven approaches, ranging from purely data-driven, sometimes called *nonparametric approaches* to semiparametric ones—where parametric and nonparametric estimators are combined. The estimation of option-implied densities can take various forms as there are many different ways to smooth a curve. Nadaraya–Watson kernel regression was used by Aït-Sahalia and Lo [3, 13, 14, 19], constrained splines by Bates [9], flexible parametric functional forms by Abadir and Rockinger [1], and neural networks by Aït-Sahalia and Duarte [2]; Bondarenko [11] and Garcia and Gençay [26], considered constrained least-square approaches. A more practitioner-oriented approach was pioneered by Jackwerth and Rubinstein [36] and Rubinstein [46] who constructed implied trees from listed option prices.

All these methods are data intensive and typically feature slow convergence rates. Only a few indices have enough liquid actively traded derivatives with a wide span of maturities and moneyness to warrant applications of these methods.

The extended method of moments (XMMs) estimator, introduced by Gagliardini *et al.* [31], extends the standard GMM to accommodate a more general set of moment restrictions. The standard GMM is based on uniform conditional moment restrictions,

such as equation (20), which are valid for any value of the conditioning variables. The XMM can handle not only the uniform moment restrictions but also the local moment restrictions that are valid only for a given value of the conditioning variables. This leads to a new field of application to derivative pricing, as the XMM can be used for reconstructing the pricing operator on a given day, by using the information in a cross section of observed traded derivative prices and a time series of underlying asset returns. To illustrate the principle of XMM, the S&P 500 index and its derivatives are considered. Suppose that an investor at date t_0 is interested in estimating the price $c_{t_0}(h, k)$ of a call option with time-to-maturity h and moneyness strike k that is currently not (actively) traded on the market. He/she has data on a time series of T daily returns of the S&P 500 index, as well as on a small cross section of current option prices $c_{t_0}(h_j, k_j)$, $j = 1, \dots, n$, of n highly traded derivatives. The XMM approach provides the estimated prices $\hat{c}_{t_0}(h, k)$ for different values of moneyness strike k and time-to-maturity h , which interpolate the observed prices of highly traded derivatives and satisfy the hypothesis of the absence of arbitrage opportunities. These estimated prices are consistent for a large number of dates T , but with a fixed, even small, number of observed derivative prices n .

A slightly less ambitious approach has been recently advocated by Eriksson *et al.* [24]. They suggest the use of the normal inverse Gaussian (NIG) family (see **Normal Inverse Gaussian Model**) to approximate an unknown distribution risk-neutral density. The appeal of the NIG family of distributions is that they are characterized by the first four moments: mean, variance, skewness, and kurtosis. These are the moments we care about in many applications, including derivative pricing. The unknown density function is approximated by matching the cumulants. The latter are obtained from the cross section of option prices using methods proposed by Bakshi *et al.* [5]. The strength of their approach is that they link the pricing of individual derivatives to the moments of the risk-neutral distribution, which has an intuitive appeal in terms of how volatility, skewness, and kurtosis of the risk-neutral distribution can explain the behavior of the derivative prices. Eriksson *et al.* [24] showed that the approximation errors are minor when compared to several option pricing models that have known densities.

Non-Gaussian Option Pricing

The affine jump-diffusion framework (*see Affine Models*) represents an important theoretical advance. Yet, it has been argued that it has its limitations, notably due to the exclusive use of compound Poisson processes to model jumps. These processes generate a finite number of jumps within a finite time interval and have accordingly been referred to as *finite activity jump processes*. The observation that asset prices actually display many small jumps on a fine timescale has led to the development of more general jump structures, which permit an infinite number of jumps to occur within any bounded time interval. Examples of infinite-activity jump models include the inverse Gaussian model of Barndorff-Nielsen [6, 7], the generalized hyperbolic class of Eberlein *et al.* [22], the variance gamma (VG) model (*see Variance-gamma Model*) of Madan and Milne [38], the generalization of VG by Carr *et al.* [15], and the finite moment log-stable model of Carr and Wu [16]. Empirical work by these authors is generally supportive of the use of infinite-activity processes as a way to model returns in a parsimonious way. The recognition that volatility is stochastic has led to further extensions of infinite-activity Lévy models (*see Barndorff-Nielsen and Shephard (BNS) Models; Time-changed Lévy Process*) by Barndorff-Nielsen and Shephard [8] and Carr and Wu [16]. However, these models often assume that changes in volatility are independent of asset returns, and consider the leverage effect only under special cases. Carr and Wu [16] used time-changed Lévy processes that generalize the affine Poisson jump diffusions by relaxing the affine structure and by allowing more general specifications of the jump structure. Since the pioneering work of Heston [32], the literature has used the characteristic function for deriving option prices. Accordingly, Carr and Wu focus on developing analytic expressions for the characteristic function of a time-changed Lévy process (*see Time-changed Lévy Process*).

Long Range Dependence

From Long to Short-range Dependency in Discrete-time Models

The widely known class of ARMA (autoregressive moving average) processes used for modeling discrete-time processes (see [5, 6]) gives a first approach to short- and long-range dependence. For instance, the model that explains the value of a variable today, say X_t , mainly via its value yesterday, X_{t-1} , up to a centered error ε_t , leads under mild conditions to a zero mean stationary dependent process $(X_t)_{t \in \mathbb{Z}}$,

$$X_t = bX_{t-1} + \varepsilon_t \quad (1)$$

for an independent, identically distributed (i.i.d) noise sequence ε and $|b| < 1$. Such a process is, short-range dependent; this means that the process quickly forgets all about its past. A more rigorous criterion is that, under stationary assumption, the correlation function $\rho_X(h) = \text{corr}(X_t, X_{t+h})$ is exponentially decreasing, with

$$|\rho_X(h)| \sim_{h \rightarrow +\infty} e^{-\vartheta h} \quad (2)$$

for positive constant ϑ , a property satisfied by equation (1) with $\vartheta = -\log(|b|)$.

Now consider the lag operator L , $LX_t = X_{t-1}$ and rewrite model (1) as follows:

$$(1 - bL)X_t = \varepsilon_t \quad (3)$$

For the above behavior to occur, it is required that $|b| < 1$. If $|b| = 1$, the process is no longer stationary, and, for example, for $b = 1$ the so-called unit root problem appears. An intermediate case of high interest is that of a fractional unit root. More precisely, set

$$(1 - L)^\alpha X_t = \varepsilon_t \quad (4)$$

where $|\alpha| < 1/2$ is not an integer. The operator $(1 - L)^\alpha$ is then defined (see [14, 15, 22]) by its series expansion

$$(1 - L)^\alpha = 1 - \sum_{k=1}^{\infty} \frac{\alpha \Gamma(k - \alpha)}{\Gamma(k + 1) \Gamma(1 - \alpha)} L^k$$

where, for positive x , $\Gamma(x) = \int_0^{+\infty} u^{x-1} e^{-u} du$ and $L^k X_t = X_{t-k}$. In that case, we recover a stationary

process (X_t) , but for large values of h ,

$$|\rho_X(h)| \sim_{h \rightarrow +\infty} Ch^{2\alpha-1} \quad (5)$$

This means that the covariance function (which is a measure of dependence between the observations) decays slowly. This can also be characterized in the frequency domain by the behavior near zero of the discrete spectral density defined by

$$f_X(\lambda) = \sigma_0^2 \sum_{h \in \mathbb{Z}} \rho_X(h) e^{i\lambda h} \quad (6)$$

The spectral density is such that $f_X(0)$ is finite positive and well defined in case (1) under $|b| < 1$, whereas

$$f(\lambda) \sim_{\lambda \rightarrow 0} C\lambda^{-2\alpha} \quad (7)$$

in case (4). Here, we can see that in the range $-1/2 < \alpha < 1/2$, two different cases arise:

- the case $-1/2 < \alpha < 0$, where $f_X(0) = 0$, and the sum of the correlations is finite—also called *intermediate-memory case*;
- the case $0 < \alpha < 1/2$, where $f_X(0) = +\infty$, and the sum of the correlations is infinite—also called *long-memory case*.

It is worth mentioning that many strategies for statistical inference (see [3]) on α are related to the expansion $\log f_X(\lambda) = C - 2\alpha \log \lambda + \text{Remainder}$, for λ small enough (see [12, 20]). Note also that standard log-likelihood methods were studied in this framework, which was new in the 1980s in the sense that many crucial standard assumptions required to obtain “good” properties of the estimators were violated (see [10, 11]).

Such models have been applied to the term structure of interest rates [1] and to foreign exchange rates [8]. However, it is well known that linear models fail to adequately represent asset returns, which have been frequently modeled using GARCH (generalized autoregressive conditionally heteroskedastic) (see **GARCH Models**) models [13]. Fractional extensions of GARCH models have been proposed to capture long-range dependence properties in the volatility process [2, 4]. More precisely, a GARCH model represents $X_t = \ln(S_t/S_{t-1})$ where S_t is an asset price as $X_t = \sigma_t \varepsilon_t$ and ε_t is a centered white-noise process

with variance 1. Then the recurrence equations

$$\sigma_t^2 = a_0 + \sum_{j=1}^p a_j X_{t-j}^2 + \sum_{k=1}^q b_k \sigma_{t-k}^2 \quad (8)$$

can be written as ARMA representations with respect to the white noise $v_t = X_t^2 - \sigma_t^2$. It is then natural to study the effect of fractional unit root in such equations, and the long-range dependence properties. The point in GARCH models is that the existence of a unit root in this framework leading to processes called IGARCH (Integrated GARCH) models can be compatible with stationarity and is a mean of modeling persistence in variance of shocks. Thus, fractional models in this context turn out to be less essential. The theoretical study of the resulting processes can be also difficult: it is already the case without long-range dependence.

It is therefore natural to formulate such models in continuous time.

Long-range-dependent Continuous-time Models in Finance

Indeed, model (4) for X_t has properties that are very similar to fractional Brownian motion (*see Fractional Brownian Motion*) increments, introduced by Mandelbrot and Van Ness [18]. More precisely, a natural analog of $(1-L)^{-\alpha} \varepsilon_t$ is $\int_0^t (t-s)^{\alpha} dB(s)$ where B is a standard Brownian motion. The integral should start at $-\infty$ for stationarity purpose, but it would not have finite variance. This is why the truncated version above is often used for modeling purposes. Fractional Brownian motion, whether truncated or not, does not have the semimartingale property. As this property is crucially required for log asset prices in continuous-time arbitrage-free models, fractional models led to problems in this regard. This was confirmed by Rogers [21] who showed the existence of arbitrage in presence of fractional Brownian motion for the log-prices. Moreover, there is no compelling empirical evidence of long memory in asset returns. But Hull and White-type [17] or stochastic volatility models lead to the idea that there was some kind of persistence in the volatility process. This persistence can be modeled by the insertion of fractional Brownian motion in the volatility equation.

Consider first a stochastic volatility model (*see Stochastic Volatility Models*) defined as a bivariate

diffusion process:

$$\begin{cases} dS_t/S_t = \mu(t, S_t)dt + \sigma_t dB_t^{(1)}, \\ \sigma_t^2 = f(\eta_t), \\ d\eta_t = m(\eta_t)dt + g(\eta_t)dB_t^{(2)} \end{cases} \quad (9)$$

where $(B_t^{(1)}, B_t^{(2)})$ is a bidimensional standard Brownian motion. Let us consider the case where $B_t^{(1)}$ and $B_t^{(2)}$ are independent. To introduce some long-range dependence in the volatility behavior, the Brownian motion driving the volatility equation can be replaced by a fractional Brownian motion. Stochastic differential equations driven by fractional Brownian motions require advanced tools for proving existence and uniqueness of solutions [7, 16, 19]. A few simple examples can be studied with more “elementary” tools (see [9]). For instance, take

$$\begin{cases} dS_t/S_t = \mu(t, S_t)dt + \sigma_t dB_t^{(1)}, \\ \sigma_t^2 = \exp(2\eta_t), \\ d\eta_t = k(\theta - \eta_t)dt + g dB_t^{(\alpha)}, \quad k, \theta, g \text{ constants} \end{cases} \quad (10)$$

where $B_t^{(\alpha)} = \int_0^t (t-s)^{\alpha} dB_s^{(2)} / \Gamma(1+\alpha)$. For simplicity, we shall set $\mu \equiv 0$ in the following. Initial conditions for σ_t can be chosen so that the process is stationary. Then, it can be checked that the process σ_t is long-range dependent when considered as continuously observed, in the sense given in equations (5) and (7), where the spectral density is now the continuous-time one (i.e., $f_X^c(\lambda) = s_0^2 \int e^{i\lambda u} \rho_X(u) du$).

Of course, the process is, in fact, discretely observed. It is worth noting that the correlation property is stable from continuous to discrete-time observations. The folding formula that links the continuous-time formula of spectral density to the discrete-time one (namely, if Δ is the sample step, $f_X(\lambda) = (1/\Delta) \sum_{n \in \mathbb{Z}} f_X^c((\lambda + 2\pi n)/\Delta)$) shows, on the other hand, that the spectral long-memory behavior is preserved when going from continuous-time observation to discrete-time sample for $0 < \alpha < 1/2$.

The additional difficulty here is that the volatility σ_t^2 process is not observed. Therefore, for statistical purpose and estimation of the parameters of the model, approximations must be used. As the first equation is standard, the quadratic variation of the observed log price process is the integrated volatility,

and therefore, if $\{t_i\}_i$ is a partition of the interval $[t, T]$, then

$$\int_t^T \sigma_u^2 du = \lim_{\max_i |t_{i+1} - t_i| \rightarrow 0} \sum_i [\ln(S_{t_{i+1}}) - \ln(S_{t_i})]^2 \quad (11)$$

where the limit holds in probability. Thus, it is possible, if high-frequency data are available, to build pseudo-observations of the process $(1/h) \int_t^{t+h} \sigma_u^2 du \sim \sigma_t^2$, for small values of h . Note that $Z_t = \int_t^{t+1} \sigma^2(u) du$ can also be consistently estimated with high-frequency data; it is stationary and long memory, with the same memory parameter α as σ^2 . Statistical inference for the parameters can then be implemented, by using Whittle contrast or more classical log-likelihood maximization.

From the point of view of option pricing, the general formula of option prices for a deterministic interest rate $r(t)$ under the no-free-lunch assumption is still valid. The call option price C_t is given by $C_t = B(t, T) \mathbb{E}^{\mathbb{Q}}[\max(0, S_T - K) | \mathcal{F}_t]$ where $B(t, T) = \exp(-\int_t^T r(u) du)$ is the price at t of a zero coupon bond of maturity T and $\mathbb{Q}$ is the probability equivalent to $\mathbb{P}$ under which the discounted price process is martingale. Then we get

$$C_t = S_t \left\{ \mathbb{E}^{\mathbb{Q}} \left[\Phi \left(\frac{m_t}{U_{t,T}} + \frac{U_{t,T}}{2} \right) \right] - e^{-m_t} \mathbb{E}^{\mathbb{Q}} \left[\Phi \left(\frac{m_t}{U_{t,T}} - \frac{U_{t,T}}{2} \right) \right] \right\} \quad (12)$$

where $m_t = \ln(S_t / (K B(t, T)))$, $U_{t,T} = \sqrt{\int_t^T \sigma_u^2 du}$ and $\Phi(u) = \int_{-\infty}^u e^{-t^2/2} dt / \sqrt{2\pi}$. The point is that the bivariate process $(\ln(S_t), \sigma_t^2)$ is no longer Markovian so that a conditional expectation given $\mathcal{F}_t$, the information set generated by the past of the process until t , does not only depend on the value of the process at time t but on the whole past of σ^2 . This is the price to pay for incorporating long-range dependence of σ^2 in the model. Practitioners are used to computing the so-called Black–Scholes implied volatility by inversion of the Black–Scholes option pricing formula on the observed option prices. It can be checked that long-memory properties are transmitted to many approximations of implied volatilities that can be deduced from the above formula, under the assumption that there is no premium for volatility risk (so

that conditional expectations under $\mathbb{Q}$ are the same as under the current probability measure $\mathbb{P}$). Then statistical strategies can be devised by using option prices, at least to estimate α , or to recover integrated volatilities.

Factor Models

Factor models of security returns decompose the random return on each of a cross section of assets into factor-related and asset-specific returns. Letting r denote the vector of random returns on n assets, and assuming k factors, a factor decomposition has the form

$$r = a + Bf + \varepsilon \quad (1)$$

where B is an $n \times k$ -matrix of factor betas, f is a random k -vector of factor returns, and ε is an n -vector of asset-specific returns. The n -vector of coefficients a is set so that $E[\varepsilon] = 0$. By defining B as the least squares projection $B = \text{cov}(r, f)C_f^{-1}$, it follows that $\text{cov}(f, \varepsilon) = 0^{k \times n}$.

The factor decomposition (1) puts no empirical restrictions on returns beyond requiring that the means and variances of r and f exist. So in this sense it is empty of empirical content. To add empirical structure, it is commonly assumed that the asset-specific returns ε are cross-sectionally uncorrelated, $E[\varepsilon\varepsilon'] = D$ where D is a diagonal matrix. This implies that the covariance matrix of returns can be written as the sum of a matrix of rank k and a diagonal matrix:

$$\text{cov}(r, r') = B\text{cov}(f, f')B' + D \quad (2)$$

This is called a *strict factor model*. Without loss of generality, one can assume that $\text{cov}(f, f')$ has rank k , since otherwise one of the factors can be removed (giving a $k - 1$ factor model) without affecting the fit of the model.

An important (and often troublesome) feature of factor models is their rotational indeterminacy. Let L denote any nonsingular $k \times k$ -matrix and consider the set of factors $f^* = Lf$ and factor betas $B^* = L^{-1}B$. Note that f^*, B^* can be used in place of f, B since only their matrix product affects returns and the linear “rotation” L disappears from this product. This means that factors f and associated factor betas B are only defined up to a $k \times k$ linear transformation. In order to empirically identify the factor model, one can set the covariance matrix of the factors equal to an identity matrix, $E[ff'] = I_k$, without loss of generality.

Approximate Factor Models

Security market returns have strong comovements, but the assumption that returns obey a strict factor model is easily rejected. In practice, for any reasonable value of k , there will be at least some discernible positive correlations between the asset-specific returns of at least some assets. An *approximate factor model* (originally developed by Chamberlain and Rothschild [7]) weakens the strict factor model of exactly zero correlations between all asset-specific returns. Instead, it assumes that there is a large number, n , of assets and the proportion of the correlations that are nonnegligibly different from zero is close to zero. This condition is formalized as a bound on the eigenvalues of the asset-specific return covariance matrix:

$$\lim_{n \rightarrow \infty} \max \text{eigval}[\text{cov}(\varepsilon, \varepsilon')] < c \quad (3)$$

for some fixed $c < \infty$. Crucially, this condition implies that asset-specific returns are *diversifiable risk* in the sense that any well-spread portfolio w will have asset-specific variance near zero:

$$\begin{aligned} \lim_{n \rightarrow \infty} w' \text{cov}(\varepsilon, \varepsilon') w &= 0 \text{ for any } w \\ \text{such that } \lim_{n \rightarrow \infty} w' w &= 0 \end{aligned} \quad (4)$$

Note that an approximate factor model uses a “large n ” modeling approach; the restrictions on the covariance matrix need only hold approximately as the number of assets n grows large.

Letting $V = \text{cov}(\varepsilon, \varepsilon')$ which is no longer diagonal, and choosing the rotation so that $\text{cov}(f, f') = I$, we can write the covariance matrix of returns as

$$\text{cov}(r, r') = BB' + V \quad (5)$$

In addition to equation (4), it is appropriate to impose the condition that $\lim_{n \rightarrow \infty} \min \text{eigval}[BB'] = \infty$. This ensures that each of the k factors represents a pervasive source of risk in the cross section of returns.

Statistical Factor Models

Financial researchers differentiate between characteristic-based, macroeconomic, and statistical factor models [2]). In a characteristic-based model, the

factor betas of asset are tied to observable characteristics of the securities, such as company size or the book-to-price ratio, or the industry categories to which each security belongs. In macroeconomic factor models, the factors are linked to the innovations in observable economic time series such as inflation and unemployment. In a statistical factor model, neither factors nor betas are tied to any external data sources and the model is identified from the covariances of asset returns alone.

Recall the convenient rotation $E[ff'] = I$ that allows us to write the strict factor model (1) as

$$\text{cov}(r, r') = BB' + D \quad (6)$$

Assuming that the cross section of return is multivariate normal and independent and identically distributed (i.i.d.) through time, the sample covariance matrix $\widehat{\text{cov}}(r, r')$ has a Wishart distribution. Imposing the strict factor model assumption (6) on the true covariance matrix, it is possible to estimate the set of parameters B, D by maximum likelihood. This maximum likelihood problem requires high-dimensional nonlinear maximization: there are $nK + n$ parameters to estimate in B, D . There is also an inequality constraint on the maximization problem: the diagonal elements of D must be nonnegative, since they represent variances. The solution to the maximum likelihood problem yields estimates of B and D , which correspond to the systematic and unsystematic risk measures. It is often the case that estimates of the time series of factors, f , are of interest. These are called *factor scores* in the statistical literature and can be obtained through cross-sectional generalized least squares (GLS) regressions of r on $\widehat{B}$

$$\widehat{f}_t = (\widehat{B}\widehat{D}^{-1}\widehat{B})^{-1}\widehat{B}\widehat{D}^{-1}r_t \quad (7)$$

See [5] for a review of the various iterative algorithms, which can be used to numerically solve the maximum likelihood factor analysis problem and estimate the factor scores. Roll and Ross [25] provide an early empirical application to equity returns data.

The first k eigenvectors of the return covariance matrix scaled by the square roots of their respective eigenvalues are called the k *principal components* of the covariance matrix. A restrictive version of the strict factor model is the *scalar factor model*, given by equation (2) plus the scalar matrix condition $D = \sigma_\varepsilon^2 I$. Under the assumption of a scalar factor model, the maximum likelihood

problem simplifies, and the principal components are the maximum likelihood estimates of the factor beta matrix B (the arbitrary choice of rotation is slightly different in this case). This provides a quick and simple alternative to maximum likelihood factor analysis, under the restrictive assumption $D = \sigma_\varepsilon^2 I$.

Asymptotic Principal Components

The maximum likelihood method of factor model estimation relies on a strict factor model assumption and a time-series sample which is large relative to the number of assets in the cross section. Standard principal components require the even stronger condition of a scalar factor model. Neither method is well suited for asset returns where the cross section tends to be very large. Connor and Korajczyk [11] develop an alternative method called *asymptotic principal components*, building on the approximate factor model theory of Chamberlain and Rothschild [7]. Connor and Korajczyk analyze the eigenvector decomposition of the $T \times T$ cross product matrix of returns rather than that of the $n \times n$ covariance matrix of returns. They show that given a large cross section, the first k eigenvectors of this cross-product matrix provide consistent estimates of the $k \times T$ matrix of factor returns. Stock and Watson [31] extend the theory to allow both large time series and large cross-sectional samples, time-varying factor betas, and provide a quasi-maximum likelihood interpretation of the technique. Bai [3] analyzes the large-sample distributions of the factor returns and factor beta matrix estimates in a generalized version of this approach.

Macroeconomic Factor Models

The rotational indeterminacy in statistical factor models makes these unsuitable for the application of factor models to many research problems. Statistical factor models do not allow the analyst to assign meaningful labels to the factors and betas; one can identify the k pervasive risks in the cross section of returns, but not what these risks represent in terms of economic and financial theory.

One approach to making the factor decomposition more interpretable is to rotate the statistical factors so that the rotated factors are maximally correlated with prespecified macroeconomic factors. If f_t is a

k -vector of statistical factors and m_t is a k -vector of macroeconomic innovations, we can regress the macroeconomic factors on the statistical factors:

$$m_t = \Pi f_t + \eta_t \quad (8)$$

As long as Π has rank k , the span of the rotated factors, Πf_t , is the span of the original statistical factors, f_t . However, the rotated factors can now be interpreted as the return factors that are correlated with the specified macroeconomic series. With this rotation the new factors are no longer orthogonal, in general. This approach is described in [12].

Alternatively, one can work with the prespecified macroeconomic series directly. Chan *et al.* [8] and Chen *et al.* [9] develop a macroeconomic factor model in which the factor innovations f are observed directly (using innovations in economic time series) and the factor betas are estimated via time-series regression of each asset's return on the time series of factors. They begin with the standard description of the current price of each asset, p_{it} , as the present discounted value of its expected cash flows:

$$p_{it} = \sum_{s=1}^{\infty} \frac{E[c_{it}]}{(1 + \rho_{st})^s} \quad (9)$$

where ρ_{st} is the discount rate at time t for expected cash flows at time $t + s$. Chen, Roll, and Ross note that the common factors in returns must be variables which cause pervasive shocks to expected cash flows $E[c_{it}]$ and/or risk-adjusted discount rates ρ_{st} . They propose inflation-, interest-rate-, and business-cycle-related variates to capture these common factors. Shanken and Weinstein [29] find that empirically the model lacks robustness in that small changes in the included factors or the sample period have large effects on the estimates. Connor [10] argues that although macroeconomic factor models are theoretically attractive since they provide a deeper explanation for return comovement than statistical factor models, their empirical fit is substantially weaker than statistical and characteristic-based models. Vassalou [33] argues, on the other hand, that the ability of the Fama–French model (see below) to explain the cross section of mean returns can be attributed to the fact that Fama–French factors provide good proxies for macroeconomic factors.

Characteristic-based Factor Models

A surprisingly powerful method for factor modeling of security returns is the characteristic-based factor model. Rosenberg [26] was the first to suggest that suitably scaled versions of standard accounting ratios (book-to-price ratio, market value of equity) could serve as factor betas. Using these predefined betas, he estimates the factor realizations f_t by cross-sectional regression of time- t asset returns on the predefined matrix of betas.

In a series of very influential papers, Fama and French [16, 17, 18] propose a two-stage method for estimating characteristic-based factor models. In the first stage, they sort assets into fractile portfolios based on book-to-price and market value characteristics. They use the differences between returns on the top and bottom fractile portfolios as proxies for the factor returns. They also include a market factor proxied by the return on a capitalization-weighted market index. In the second stage, the factor betas of portfolios and/or assets are estimated by time-series regression of asset returns on the derived factors. Carhart [6] and Jegadeesh and Titman [22, 23] show that the addition of a momentum factor (proxied by high 12-month return minus low 12-month return) adds explanatory power to the Fama–French three-factor model, both in terms of explaining comovements and mean returns. Goyal and Santa-Clara [19] and Ang *et al.* [1, 2] also find evidence for an own-volatility-related factor, for explaining both return comovements and mean returns.

Industry–Country Components Models

One of the most empirically powerful factor decompositions for equity returns is an error-components model using industry affiliations. This involves setting the factor beta matrix equal to zero/one dummies, with row i containing a one in the j th column if and only if firm i belongs to industry j . This is the simplest type of characteristic-based factor model of equity returns.

The first statistical factor is dominant in equity returns, accounting for 80–90% of the explanatory power in a multifactor model. The standard specification of an error-components model does not isolate the “first” factor since its influence is spread across the factors. Heston and Rouwenhorst [20] describe an alternative specification in which this factor is

separated from the k industry factors. They add a constant to the model, so that the expanded set of factors $k + 1$ is not directly identified (this lack of identification is sometimes called the dummy variable trap, referring to a model that includes a full set of zero-one dummies plus a constant). Heston and Rouwenhorst, impose an adding-up restriction on the estimated $k + 1$ factors: the set of industry factors must sum to zero. This adding-up restriction on the factors restores statistical identification to the model, requiring constrained least squared in place of standard least squares estimation. It also provides a useful interpretation of the estimated factors: the factor associated with the constant term is the “marketwide” or “first” factor, and the factors associated with the industry dummies are the extra-market industry factors. This specification has been widely adopted in the literature.

Heston and Rouwenhorst’s adding-up condition is particularly useful in a multicountry context. It allows one to include an overlapping set of country and industry dummies without encountering the problem of the dummy variable trap. Including a constant, an international industry–country factor model must impose adding-up conditions both on the estimated industry factors and on the estimated country factors. This type of country–industry specification is useful, for example, in measuring the relative contribution of cross-border and national influences to return comovements; see, for example, [21].

Determining the Number of Factors

In the case of maximum likelihood estimation of a strict factor model, it is possible to test for the correct number of factors by comparing the likelihood of the model with k factors to that of a $k + 1$ factor model. Under the standard assumptions, for large time-series samples, the ratio of the log likelihoods has an approximate chi-squared distribution. There are drawbacks to this test in the context of asset returns data and its performance has been problematic; see, for example, [14, 15], and [28], in which the test is found to be unreliable. The test may rely too strongly on the assumption of a strict factor model (an exactly diagonal covariance matrix of asset-specific returns), which is at best a convenient fiction in the case of asset returns. Also, it tests the hypothesis that the correct number of factors has been prespecified,

rather than optimally determining the best number of factors to use.

Connor and Korajczyk [13] derive a test for the number of factors, which is robust to having an approximate, rather than strict factor model. It is based on the decline in average idiosyncratic variance as additional factors are added.

Bai and Ng [4] take a different approach to the factor-number decision. They view the choice of the number of factors as a model selection problem, and build on the Akaike and Bayesian information criteria (BIC) information criteria-based tests for model selection. Bai and Ng compute the average asset-specific variance (both across time and across securities) in a model with k factors:

$$\sigma_\varepsilon^2(k) = \frac{1}{nT} \sum_{i=1}^n \sum_{t=1}^T \hat{\varepsilon}_{it}^2 \quad (10)$$

The Bai–Ng procedure involves choosing k to minimize a degrees-of-freedom adjusted variant of average asset-specific variance:

$$k^* = \arg \min \sigma_\varepsilon^2 + kg(n, T) \quad (11)$$

where the penalty function $g(n, T)$ serves to compensate for the lost degrees of freedom when estimating the model with more factors.

Factor Beta Pricing Theory

A central concern in asset pricing theory is the determination of asset risk premia and their connection to sources of pervasive risk. Factor models have been central to this research area. In a factor beta pricing model, the expected return of each asset equals the risk-free return plus a linear combination of the factor betas of the assets, with the linear weights (factor risk premia) constant across securities:

$$E[r] = 1^n r_0 + B\pi \quad (12)$$

where r_0 is the risk-free return and π is a k –vector of factor risk premia. Important special cases include the capital asset pricing model [30] (Treynor, J.L. (1961). *Toward a Theory of Market Value of Risky Assets*. (unpublished working paper).) [32], the arbitrage pricing theory [27], the Fama–French model [17, 18], and [24] intertemporal capital asset pricing model.

Generalized Method of Moments (GMM)

The generalized method of moments (GMM) provides a computationally convenient method of obtaining consistent and asymptotically normally distributed estimators of the parameters of statistical models. The method has been applied in many areas of economics but has arguably been most frequently applied in finance. In fact, it was in empirical finance that the power of the method was first illustrated: for while Hansen [7] introduced GMM and presented its fundamental statistical theory, Hansen and Hodrick [9] and Hansen and Singleton [10] showed the potential of the GMM approach to estimation through their empirical analyses of, respectively, foreign exchange markets and asset pricing. This article briefly describes the GMM framework for estimation and inference in the case where time-series data are used. The reader is referred to [6] for a comprehensive treatment of GMM that presents both a rigorous statistical analysis of the method and empirical illustrations in finance. For applications of GMM to panel data, see [15].

The popularity of GMM can be understood by comparing the requirements for the method to those for maximum likelihood (ML). While ML is the best available estimator within the paradigm of classical statistics, its optimality stems from its basis on the joint probability distribution of the data. However, in many scenarios of interest in finance, this dependence on the probability distribution can become a weakness for two main reasons. First, in some models, the joint probability distribution is only implicitly specified and is not available in a convenient closed form with the result that ML is computationally infeasible, for example, in stochastic volatility models [11]. Secondly, in other cases, the underlying theoretical model places restrictions on the distribution of the data but does not completely specify its form, with the result that ML is infeasible unless the researcher imposes an arbitrary assumption about the distribution. The latter is an unattractive strategy because if the assumed distribution is incorrect, then the optimality of ML is lost, and the resulting estimator may even be inconsistent; for example, in nonlinear Euler equation models [10]. In contrast, GMM estimation is based on population moment conditions. It turns

out that in many cases where the financial-theoretic model does not specify the complete distribution, it does specify population moment conditions. Therefore, in these settings, GMM can be preferred to ML because it offers a way to estimate the parameters solely on the basis of information deduced from the underlying financial model.

The cornerstone of GMM estimation is the population moment condition:

Definition 1 Population Moment Condition.

Let θ_0 be a vector of unknown parameters that are to be estimated, $\mathbf{v}_t$ be a vector of random variables, and $\mathbf{f}(\cdot)$ a vector of functions. Then a population moment condition takes the form

$$E[\mathbf{f}(\mathbf{v}_t, \theta_0)] = 0 \quad (1)$$

for all t .

To illustrate the types of population moment conditions that can arise in finance models, we consider the specific examples in the seminal papers [9] and [10].

Example 1 The efficiency of foreign exchange markets

Consider the following regression model for the relationship between the forward and spot exchange rates:

$$s_{t+k} = \beta_{0,1} + \beta_{0,2}f_{t,k} + u_t \quad (2)$$

where $f_{t,k}$ is the log of the k -period forward exchange rate at time t , s_{t+k} is the log of the spot exchange rate in period $t+k$, $\beta_{0,1}$ and $\beta_{0,2}$ are unknown parameters, and u_t is an error term. Hansen and Hodrick [9] demonstrate that under the simple efficient-markets hypothesis, the following population moment condition holds

$$E[f_{t,k}(s_{t+k} - \beta_{0,1} - \beta_{0,2}f_{t,k})] = 0 \quad (3)$$

where $(\beta_{0,1}, \beta_{0,2}) = (0, 1)$.

Example 2 The consumption-based asset-pricing model

The consumption-based asset-pricing model involves a representative agent who makes investment and consumption decisions at time t to maximize his/her discounted lifetime utility subject to a budget constraint. Assuming that the agent's utility function is of the constant relative risk aversion form and that the

only asset available as a possible investment yields a pay-off in the following period, Hansen and Singleton [10] show that the model implies the following population moment condition:

$$E \left[\mathbf{z}_t \left\{ \delta_0 \left(\frac{c_{t+1}}{c_t} \right)^{\gamma_0-1} \left(\frac{g_{t+1}}{p_t} \right) - 1 \right\} \right] = 0 \quad (4)$$

where c_t is consumption in period t , g_{t+1} is the gain (cash flow) on the asset in period $t+1$, p_t is the price of the asset in period t , $\mathbf{z}_t$ is a vector of variables in the agent's information set at time t , and the unknown parameters $1 - \gamma_0$ and δ_0 are, respectively, the agent's coefficient of relative risk aversion and discount factor.

The population moment condition states that $E[\mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta})]$ equals zero when evaluated at $\boldsymbol{\theta}_0$. For the GMM estimation to be successful, this must be a unique property of $\boldsymbol{\theta}_0$, that is, $E[\mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta})]$ is not equal to zero when evaluated at any other value of $\boldsymbol{\theta}$. If the latter holds, then $\boldsymbol{\theta}_0$ is said to be *identified* by $E[\mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta}_0)] = 0$. A first-order condition for identification (often referred to as a *local condition*) is that $\text{rank}\{\mathbf{G}(\boldsymbol{\theta}_0)\} = p$, where $\mathbf{G}(\boldsymbol{\theta}) = E[\partial \mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta}) / \partial \boldsymbol{\theta}']$, and this plays a crucial role in standard asymptotic distribution theory for GMM. By definition, the moment condition involves q pieces of information about p unknowns; therefore identification can only hold if $q \geq p$. For reasons that emerge below, it is convenient to split this scenario into two parts: $q = p$, in which case $\boldsymbol{\theta}_0$ is said to be *just identified*, and $q > p$, in which case $\boldsymbol{\theta}_0$ is said to be *overidentified*.

Let $\mathbf{g}_T(\boldsymbol{\theta})$ be the analogous sample moment to $E[\mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta})]$, that is, $\mathbf{g}_T(\boldsymbol{\theta}) = T^{-1} \sum_{t=1}^T \mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta})$ where T is the sample size. The GMM estimator is then as follows.

Definition 2 Generalized Method of Moments Estimator.

The generalized method of moments estimator based on equation (1) is the value of $\boldsymbol{\theta}$ that minimizes

$$Q_T(\boldsymbol{\theta}) = \mathbf{g}_T(\boldsymbol{\theta})' \mathbf{W}_T \mathbf{g}_T(\boldsymbol{\theta}) \quad (5)$$

where $\mathbf{W}_T$ is known as the weighting matrix and is restricted to be a positive semidefinite matrix that converges in probability to $\mathbf{W}$, some positive definite matrix of constants.

The restrictions on the weighting matrix are required to ensure that $Q_T(\boldsymbol{\theta})$ is a meaningful measure of the distance the sample moment is from zero at different values of $\boldsymbol{\theta}$. The choice of weighting matrix is discussed further below.

The first-order conditions for this minimization are

$$\mathbf{G}_T(\hat{\boldsymbol{\theta}}_T)' \mathbf{W}_T \mathbf{g}_T(\hat{\boldsymbol{\theta}}_T) = 0 \quad (6)$$

where $\mathbf{G}_T(\boldsymbol{\theta}) = T^{-1} \sum_{t=1}^T \partial \mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta}) / \partial \boldsymbol{\theta}'$. The structure of these conditions reveals some interesting insights into GMM estimation. Since $\mathbf{G}_T(\boldsymbol{\theta})$ is $q \times p$, it follows that equation (6) involves calculating $\hat{\boldsymbol{\theta}}_T$ as the value of $\boldsymbol{\theta}$ that sets the p linear combinations of $\mathbf{g}_T(\cdot)$ to zero. Therefore, if $p = q$ (and $\mathbf{G}_T(\hat{\boldsymbol{\theta}}_T)' \mathbf{W}_T$ is nonsingular), then $\hat{\boldsymbol{\theta}}_T$ satisfies the analogous sample moment condition to equation (1), $\mathbf{g}_T(\hat{\boldsymbol{\theta}}_T) = 0$, and is, thus, the method of moments estimator based on the original moment condition. However, if $q > p$, then the first-order conditions are not equivalent to solving the sample moment condition. Instead, $\hat{\boldsymbol{\theta}}_T$ is equivalent to the method of moments estimator based on

$$\mathbf{G}(\boldsymbol{\theta}_0)' \mathbf{W} E[\mathbf{f}(\mathbf{v}_t, \boldsymbol{\theta}_0)] = 0 \quad (7)$$

Although equation (1) implies equation (7), the reverse does not hold because $q > p$; therefore, in this case, the estimation is actually based on only part of the original information. As a result, if $q > p$, then GMM can be viewed as decomposing the original moment condition into two parts, the *identifying restrictions*, which contain the information actually used in the estimation, and the *overidentifying restrictions*, which represent a remainder. Furthermore, GMM estimation produces two fundamental statistics each of which is associated with a particular component: the estimator $\hat{\boldsymbol{\theta}}_T$ is a function of the information in the identifying restrictions, and the estimated sample moment, $\mathbf{g}_T(\hat{\boldsymbol{\theta}}_T)$, is a function of the information in the overidentifying restrictions. While unused in estimation, the overidentifying restrictions play a crucial role in inference about the validity of the model as discussed below.

To establish the consistency and asymptotic normality of the GMM estimator, it is necessary to place restrictions on $\mathbf{v}_t$ and $\mathbf{f}(\cdot)$. In the standard asymptotic framework (see [7]), it is assumed that $\mathbf{v}_t$ is stationary and ergodic, $\mathbf{f}(\cdot)$ is continuous and differentiable and that its derivative is continuous in $\boldsymbol{\theta}$. Various expectations of $\mathbf{f}(\cdot)$ and its derivative must also exist.

These conditions permit the applications of laws of large numbers and central limit theorems to the requisite sample averages. Chief among the restrictions on expectations of $\mathbf{f}(\cdot)$ are that the population moment condition is valid and identifies θ_0 . Under the above conditions, it can be shown that the $\hat{\theta}_T \xrightarrow{p} \theta_0$ and

$$T^{1/2}(\hat{\theta}_T - \theta_0) \xrightarrow{d} N(0, V) \quad (8)$$

where

$$V = [\mathbf{G}(\theta_0)' \mathbf{W} \mathbf{G}(\theta_0)]^{-1} \mathbf{G}(\theta_0)' \mathbf{W} \mathbf{S}(\theta_0) \mathbf{W} \mathbf{G}(\theta_0) \\ \times [\mathbf{G}(\theta_0)' \mathbf{W} \mathbf{G}(\theta_0)]^{-1}$$

and $\mathbf{S}(\theta) = \lim_{T \rightarrow \infty} \text{Var}[T^{1/2} \mathbf{g}_T(\theta)]$.

At this point, we return to the issue of the choice of weighting matrix. In the discussion of the first-order conditions above, it is noted that if $p = q$, then the GMM estimator can be found by solving $\mathbf{g}_T(\hat{\theta}_T)$. As a result, the estimator does not depend on $\mathbf{W}_T$. The asymptotic properties must also be invariant to $\mathbf{W}_T$ and it can be shown that $\mathbf{V}$ reduces to $\{\mathbf{G}(\theta_0)' \mathbf{S}(\theta_0)^{-1} \mathbf{G}(\theta_0)\}^{-1}$ in this case. However, if $q > p$, then the first-order conditions depend on $\mathbf{W}_T$ and therefore so does $\hat{\theta}_T$, in general. This dependence is unattractive because it raises the possibility that subsequent inferences can be affected by the choice of weighting matrix. However, in terms of asymptotic properties, the choice of weighting matrix only manifests itself in $\mathbf{V}$, the asymptotic variance of the estimator. Since this is the case, it is natural to choose $\mathbf{W}_T$ such that $\mathbf{V}$ is minimized in a matrix sense. Hansen [7] shows that this can be achieved by setting $\mathbf{W}_T = \hat{\mathbf{S}}_T^{-1}$ where $\hat{\mathbf{S}}_T$ is a consistent estimator of $\mathbf{S}(\theta_0)$. The resulting asymptotic variance is $\mathbf{V} = \mathbf{V}^0 = \{\mathbf{G}(\theta_0)' \mathbf{S}(\theta_0)^{-1} \mathbf{G}(\theta_0)\}^{-1}$; Chamberlain [4] shows $\mathbf{V}^0$ is a semiparametric efficiency bound for estimation of θ_0 based on equation (1).

In practical terms, two issues arise in the implementation of GMM with this choice of weighting matrix: (i) how to construct $\hat{\mathbf{S}}_T$ so that it is a consistent estimator of $\mathbf{S}(\theta_0)$; (ii) how to handle the dependence of $\hat{\mathbf{S}}_T$ on $\hat{\theta}_T$. We treat each in turn.

(i) Estimation of $\mathbf{S}(\theta_0)$.

Under stationarity and ergodicity and certain other technical restrictions, it can be shown that $\mathbf{S}(\theta_0) = \Gamma_0(\theta_0) + \sum_{i=1}^{\infty} \{\Gamma_i(\theta_0) + \Gamma_i(\theta_0)'\}$ where $\Gamma_i(\theta_0) = \text{Cov}[\mathbf{f}(\mathbf{v}_t, \theta_0), \mathbf{f}(\mathbf{v}_{t-i}, \theta_0)]$ is known as the i -lag autocovariance matrix of $\mathbf{f}(\mathbf{v}_t, \theta_0)$ [2]. In some cases, the

structure of the model implies $\Gamma_i(\theta_0) = 0$ for all $i > k$ for some k , and this simplifies the estimation problem ([6], Section 3.5). In the absence of such a restriction on the autocovariance matrices, the long-run variance can be estimated by a member of the class of *heteroscedasticity autocorrelation covariance (HAC)* estimators defined by

$$\hat{\mathbf{S}}_{\text{HAC}} = \hat{\mathbf{r}}_0 + \sum_{i=1}^{T-1} \omega(i; b_T) (\hat{\mathbf{r}}_i + \hat{\mathbf{r}}_i') \quad (9)$$

where $\hat{\mathbf{r}}_j = T^{-1} \sum_{t=j+1}^T \hat{\mathbf{r}}_t \hat{\mathbf{r}}_{t-j}'$, $\hat{\mathbf{r}}_t = \mathbf{f}(\mathbf{v}_t, \hat{\theta}_T)$, $\omega(\cdot)$ is known as the *kernel*, and b_T is known as the *bandwidth*. The kernel and bandwidth must satisfy certain restrictions to ensure $\hat{\mathbf{S}}_{\text{HAC}}$ is both consistent and positive semidefinite. As an illustration, Newey and West [13] propose the use of the kernel $\omega(i, b_T) = \{1 - i/(b_T + 1)\} \mathcal{I}\{i \leq b_T\}$ where $\mathcal{I}\{i \leq b_T\}$ is an indicator variable that takes the value 1 if $i \leq b_T$ and 0, otherwise. This choice is an example of a truncated kernel estimator because the number of included autocovariances is determined by b_T . For consistency, we require $b_T \rightarrow \infty$ with $T \rightarrow \infty$ but $b_T = o(T^{1/2})$. Various choices of kernel have been proposed and their properties analyzed: while theoretical rankings are possible, the evidence suggests that the choice of b_T is a far more important determinant of finite sample performance. Andrews [2] and Newey and West [14] propose data-based methods for the selection of b_T . See ([6], Section 3.5) for further discussion.

(ii) Dependence of $\hat{\mathbf{S}}_T$ on $\hat{\theta}_T$.

As is apparent from the above discussion, the calculation of a consistent estimator for $\mathbf{S}(\theta_0)$ requires knowledge of a (consistent) estimator of θ_0 . Therefore, to calculate a GMM estimator that attains the efficiency bound, a multistep procedure is used. In the first step, GMM is performed with an arbitrary weighting matrix; this preliminary estimator is then used in the calculation of $\hat{\mathbf{S}}_T$. In the second step, GMM estimation is performed with $\mathbf{W}_T = \hat{\mathbf{S}}_T^{-1}$. For obvious reasons, the resulting estimator is commonly referred to as the *two-step GMM estimator*. Instead of stopping after just two steps, the procedure can be continued so that on the i th step the GMM estimation is performed using $\mathbf{W}_T = \hat{\mathbf{S}}_T^{-1}$, where $\hat{\mathbf{S}}_T$ is based on the estimator from the $(i - 1)$

th step. This yields the so-called *iterated GMM estimator*.

While two steps are sufficient to attain the efficiency bound, simulation evidence suggests that there are often considerable gains to iteration in the sense of improvements in the quality of asymptotic theory as an approximation to finite sample behavior ([6], Chapter 6). Notwithstanding these improvements, there is evidence that the quality of the asymptotic approximation may be poor in some circumstances of interest and this motivated the development of alternative methods for attaining the efficiency bound. One such method is the *continuous-updating generalized method of moments (CUGMM) estimator* proposed by Hansen et al. [8]. The CUGMM estimator is the value of θ that minimizes $\mathbf{g}_T(\theta)' \mathbf{S}_T(\theta)^{-1} \mathbf{g}_T(\theta)$ where $\mathbf{S}_T(\theta)$ is a (matrix) function of θ such that $\mathbf{S}_T(\theta) \xrightarrow{p} \mathbf{S}(\theta)$ uniformly in θ . While the CUGMM estimator has the same limiting distribution as the iterated GMM estimator, Newey and Smith [12] and Anatolyev [1] demonstrate analytically that the continuous-updating estimator can be expected to exhibit lower finite sample bias than its two-step counterpart; see also [3].

The foregoing results are predicated on the assumption that equation (1) represents valid information about θ_0 , and, in this sense, that the model is correctly specified. In practice, it is desirable to assess whether the data appear consistent with the restriction implied by the population moment condition. As noted above, if $p = q$, then the first-order conditions force $\mathbf{g}_T(\hat{\theta}_T) = 0$ irrespective of whether equation (1) holds, and so the latter cannot be tested directly using the estimated sample moment, $\mathbf{g}_T(\hat{\theta}_T)$. However, if $q > p$, then $\mathbf{g}_T(\hat{\theta}_T) \neq 0$ because GMM estimation only imposes the identifying restrictions and ignores the overidentifying restrictions. The latter represent $q - p$ restrictions which are true if equation (1) is itself true. To motivate the most commonly applied test statistic, it is useful to recall two aspects of our discussion above: (i) the GMM minimand measures the distance of $\mathbf{g}_T(\theta)$ from zero; and (ii) the estimated sample moment contains information about overidentifying restrictions. Combining (i) and (ii), it can be shown that GMM minimand evaluated at $\hat{\theta}_T$ is a measure of how far the sample is from satisfying the overidentifying restrictions. This leads to the *overidentifying restrictions test*

statistic,

$$J_T = T \mathbf{g}_T(\hat{\theta}_T)' \hat{\mathbf{S}}_T^{-1} \mathbf{g}_T(\hat{\theta}_T) \quad (10)$$

which converges to a χ_{q-p}^2 distribution under the null hypothesis that equation (1) holds. Notice that J_T is conveniently calculated as the sample size times the two-step (or iterated) GMM minimand evaluated at the associated estimator. The overidentifying restrictions test is the standard model diagnostic within the GMM framework. Nevertheless, J_T does not have power against all alternatives of interest: Ghysels and Hall [5] show that J_T has no (local) power against parameter variation and so it is prudent to complement the overidentifying restrictions test with tests of structural stability ([6], Section 5.4).

As noted above, there is evidence that in some cases of interest, the aforementioned (standard) asymptotic theory can provide a poor approximation to the finite sample performance of the GMM estimator and its associated inference techniques. This has prompted researchers to develop ways of ameliorating these deficiencies. The proposed methods fall into three basic categories: (i) methods for *moment selection*, which are designed to determine the “best” set of moments to use with a view to then basing inference on the standard asymptotic theory described above; (ii) resampling methods such as the *bootstrap* that are valid under similar assumptions to the standard theory but aim to provide more accurate approximations to finite sample behavior; and (iii) *alternative asymptotic theories* that are based on different assumptions to the standard framework and are designed to provide more accurate approximations in certain scenarios of interest, such as *weak identification*. For further discussion of (i)–(iii), see ([6], Chapters 6, 7, and 8).

ALASTAIR R. HALL

Stochastic Volatility Models

The Black–Scholes model (*see* **Black–Scholes Formula**) rests upon a number of assumptions that are, to some extent, “counterfactual”. Among these are continuity in time of the asset price process (they do not jump), the ability to hedge continuously without transaction costs, independent Gaussian returns, and constant volatility. Stochastic volatility models relax the last assumption by allowing volatility to be randomly varying; this is motivated by the following reason: the dependence of Black–Scholes implied volatilities computed from market prices of call and put options, known as *the smile curve* (*see* **Implied Volatility Surface**), is accounted for by stochastic volatility models. In other words, this modification of the Black–Scholes theory succeeds in one area where the classical model fails. In fact, it has been shown [18, 23] that any randomness in volatility produces a smile of implied volatilities. Empirical evidence for the smile curve of implied volatility appears in many studies, including [20], using data from before the 1987 crash, and in [16], where the postcrash skew is documented (*see* **Implied Volatility Surface**). Early work on fitting an implied volatility surface, includes [1], and [4, 6, 21]. An extensive empirical study of the stability of the fitted surfaces can be found in [5].

In fact, modeling volatility as a stochastic process is motivated *a priori* by empirical studies of stock price returns in which estimated volatility is observed to exhibit “random” characteristics. Additionally, the effects of transaction costs show up, under many models, as uncertainty in the volatility; fat-tailed returns distributions can be simulated by stochastic volatility; market “jump” phenomena are often best modeled as volatility jump processes. Stochastic volatility modeling is therefore more than a simple fix to one particular Black–Scholes assumption, but rather a powerful modification that describes a much more complex market.

Pricing derivatives in a market with stochastic volatility is an incomplete markets problem, a distinction explained below, and one which has far-reaching consequences, particularly for the hedging problem and the problem of parameter estimation. It is the

latter *inverse* problem that is the biggest mathematical and practical challenge introduced by such models.

Early surveys can be found in [9, 11], or [14], and books on stochastic volatility are also available [7, 17], and [10].

In most stochastic volatility models, the asset price $(X_t)_{t \geq 0}$ satisfies the stochastic differential equation

$$dX_t = \mu X_t dt + \sigma_t X_t dW_t \quad (1)$$

where $(\sigma_t)_{t \geq 0}$ is called the volatility process. It must satisfy some regularity conditions for the model to be well defined, but it does not have to be an Itô process: it can be a jump process, a Markov chain, and so on. In order for it to be a volatility, it should be positive. Unlike the implied deterministic volatility models (*see* **Local Volatility Model**), the volatility process is *not* perfectly correlated with the Brownian motion (W_t) . Therefore, volatility is modeled to have an independent random component of its own. This leads to an incomplete market, that is, derivatives cannot, in general, be perfectly hedged by trading the underlying asset and money market only. In fact, there is no *unique* equivalent martingale measure.

Mean-reverting Stochastic Volatility Models

Typically, volatility is taken to be an Itô process satisfying a stochastic differential equation driven by a second Brownian motion. This is the easiest way to incorporate correlation with stock price changes. One desirable feature is *mean reversion*. The term *mean reversion* refers to the characteristic (typical) time it takes for a process to get back to the mean level of its invariant distribution (the long-run distribution of the process) and “forget” about its past. From a financial modeling perspective, mean reverting refers to a linear pull-back term in the drift of the volatility process itself, or in the drift of some (underlying) process of which volatility is a function. Let us denote $\sigma_t = f(Y_t)$ where f is some positive function. Then mean-reverting stochastic volatility means that the stochastic differential equation for (Y_t) has the following form:

$$dY_t = \alpha(m - Y_t)dt + \cdots d\hat{Z}_t \quad (2)$$

where $(\hat{Z}_t)_{t \geq 0}$ is a Brownian motion correlated with (W_t) : $d\langle W, \hat{Z} \rangle_t = \rho dt$, with $|\rho| \leq 1$. It is often found

from financial data that $\rho < 0$, and there are economic arguments for a negative correlation or *leverage effect* between stock price and volatility shocks. From common experience and empirical studies, when volatility goes up, asset prices tend to go down. Some common driving processes (Y_t) are

LN Lognormal (non-mean-reverting):

$$dY_t = c_1 Y_t dt + c_2 Y_t d\hat{Z}_t \quad (3)$$

OU Ornstein–Uhlenbeck:

$$dY_t = \alpha(m - Y_t)dt + \beta d\hat{Z}_t \quad (4)$$

CIR Feller or Cox–Ingersoll–Ross:

$$dY_t = \kappa(m' - Y_t)dt + v\sqrt{Y_t}d\hat{Z}_t \quad (5)$$

Some models studied in the literature are listed in Table 1.

Classical references investigating specific stochastic volatility models are [2, 13, 15, 22, 24], and [25]. These particular models are chosen for their nice properties (e.g., positivity and mean reversion) and analytical tractability, rather than from deeper financial reasons. The Heston model is very popular for its computational tractability.

Probability density functions of the stock price obtained from simulations exhibit fatter tails because of the random volatility. In particular, the negative correlation causes the tails to be asymmetric: the left tail is fatter.

Option Pricing

Suppose first that there is an equivalent martingale measure $\mathbb{P}^*$ under which the discounted stock price

Table 1 Stochastic volatility models

Authors	Correlation	$f(y)$	Y Process
Hull–White	$\rho = 0$	$f(y) = \sqrt{y}$	Lognormal
Scott	$\rho = 0$	$f(y) = e^y$	Mean-reverting OU
Stein–Stein	$\rho = 0$	$f(y) = y $	Mean-reverting OU
Ball–Roma	$\rho = 0$	$f(y) = \sqrt{y}$	CIR
Heston	$\rho \neq 0$	$f(y) = \sqrt{y}$	CIR

$e^{-rt}X_t$ is a martingale. Then, if we price any (and all) derivatives with maturity time T and payoff H using the formula $V_t = \mathbb{E}^*\{e^{-r(T-t)}H|\mathcal{F}_t\}$, for all $t \leq T$ where $(\mathcal{F}_t)$ is the filtration generated by the two Brownian motions, then there is no arbitrage opportunity. Thus V_t is a possible price for the claim. Equivalent martingale measures are constructed by rewriting $\hat{Z}_t = \rho W_t + \sqrt{1 - \rho^2}Z_t$ where W and Z are independent standard Brownian motions under the physical measure $\mathbb{P}$, and by setting

$$W_t^* = W_t + \int_0^t \frac{(\mu - r)}{f(Y_s)} ds, \quad Z_t^* = Z_t + \int_0^t \gamma_s ds \quad (6)$$

The shift of the second independent Brownian motion does not affect the drift of X_t . By Girsanov’s theorem, (W^*) and (Z^*) are independent standard Brownian motions under a measure $\mathbb{P}^{*(\gamma)}$ defined by

$$\begin{aligned} \frac{d\mathbb{P}^{*(\gamma)}}{d\mathbb{P}} &= \exp\left(-\frac{1}{2} \int_0^T ((\theta_s^{(1)})^2 + (\theta_s^{(2)})^2) ds \right. \\ &\quad \left. - \int_0^T \theta_s^{(1)} dW_s - \int_0^T \theta_s^{(2)} dZ_s \right), \\ \theta_t^{(1)} &= \frac{\mu - r}{f(Y_t)}, \quad \theta_t^{(2)} = \gamma_t \end{aligned} \quad (7)$$

Here (γ_t) is *any* adapted (and suitably regular) process. Technically, one needs to make an assumption on the pair $(\frac{\mu - r}{f(Y_t)}, \gamma_t)$ so that $\mathbb{P}^{*(\gamma)}$ is well defined as a probability measure. In particular, this is the case if μ may depend on Y_t in such a way that the Sharpe ratio $\frac{\mu(Y_t) - r}{f(Y_t)}$ and γ_t are bounded. Then, under $\mathbb{P}^{*(\gamma)}$, the stochastic differential equations (1, 2) become

$$dX_t = rX_t dt + f(Y_t)X_t dW_t^* \quad (8)$$

$$dY_t = [\alpha(m - Y_t) - \beta\Lambda] dt + \beta d\hat{Z}_t^* \quad (9)$$

where $\hat{Z}_t^* = \rho W_t^* + \sqrt{1 - \rho^2}Z_t^*$, and $\Lambda = \rho \frac{(\mu - r)}{f(Y_t)} + \gamma_t \sqrt{1 - \rho^2}$. Any allowable choice of γ leads to an equivalent martingale measure $\mathbb{P}^{*(\gamma)}$ and to the *no-arbitrage* derivative prices

$$V_t = \mathbb{E}^{*(\gamma)}\{e^{-r(T-t)}H|\mathcal{F}_t\} \quad (10)$$

where the conditional expectation is taken with respect to the filtration generated by the two Brownian motions. In the Markovian case, $V_t = P(t, X_t, Y_t)$ where $P(t, x, y)$ is the solution of the pricing partial differential equation (PDE) obtained by the *Feynman–Kac formula*.

Special Case: Uncorrelated Volatility

It turns out that the $\rho = 0$ case is much easier to handle mathematically. In equity markets, it is widely believed $\rho < 0$, but some studies suggest ρ is close to zero in foreign-exchange data. We now assume $\rho = 0$ and (γ_t) is independent of the Brownian motion (W_t) driving the stock price so that under the risk-neutral probability $IP^{*(\gamma)}$ the volatility remains uncorrelated with (W_t) . The pricing formula (10) can be simplified under these assumptions. We can condition on the path of the volatility process and by iterated expectations, the price of a call option, for example, is then given by

$$C(t, X_t, Y_t) = \mathbb{E}^{*(\gamma)} \left\{ \mathbb{E}^{*(\gamma)} \{ e^{-r(T-t)} (X_T - K)^+ \times [\mathcal{F}_t, \sigma_s, t \leq s \leq T] | \mathcal{F}_t \} \right\} \quad (11)$$

The inner expectation is just the Black–Scholes computation with a time-dependent volatility. The answer is the Black–Scholes formula with appropriately averaged volatility, leading to the *Hull–White formula*:

$$C(t, x, y) = \mathbb{E}^{*(\gamma)} \left\{ C_{BS}(t, x; K, T; \sqrt{\overline{\sigma^2}}) | Y_t = y \right\} \quad (12)$$

where

$$\overline{\sigma^2} = \frac{1}{T-t} \int_t^T f(Y_s)^2 ds \quad (13)$$

and, for simplicity, we have assumed (Y_t) is a Markov process. Thus $\sqrt{\overline{\sigma^2}}$ is the root-mean-square time average of $\sigma(\cdot)$ over the remaining trajectory of each realization, and the call option price is the average over all possible volatility paths. This formula admits a generalization in the correlated case obtained simultaneously in [19] and [26].

Summary

The positive aspects of the stochastic volatility approach are as follows:

- It directly models the observed random behavior of market volatility.
- It allows to reproduce more realistic returns distributions, in particular fatter-than-lognormal tails.
- The asymmetry of the distribution is easily incorporated by correlating the noise sources.
- The smile/skew effect in option prices is exhibited in stochastic volatility models, where the correlation controls the skew.
- Stochastic volatility has also been successfully used in fixed income, foreign exchange, and credit markets.

However, new difficulties are associated with this approach:

- Volatility is not directly observed. As a consequence, estimation of the parameters of a specific model and the current level of volatility is not straightforward.
- There is no canonical stochastic volatility model that is generally accepted and the relevance of explicit formulas for particular models is not obvious.
- We have to deal with an incomplete market, which means that derivatives cannot be perfectly hedged with just the underlying. In addition, a volatility risk premium has to be estimated from option prices.
- Besides the choice of a particular model and its calibration, pricing with stochastic volatility models is a real challenge requiring sophisticated numerical methods. Various approximation techniques have also been proposed such as regular and singular perturbation methods in [7] and [8], WKB expansion for SABR models in [12], or small-time asymptotics in [3].

Duration Models

Duration models appear when studying the moment in time that certain events occur. Next to general applications in economics and medical sciences, their financial applications are in the more specific field of market microstructure (transaction times of assets or derivatives in a given market), and also in corporate governance (tenure of management).

Denote the unknown times at which the events of interest occur as T_i , $i = 1, \dots, n$. Almost invariably in the literature, it is assumed that the times T_i form an *increasing* sequence of *stopping times*. The random times are increasing if $T_{i+1} \geq T_i$ (almost surely (a.s.)). In that case, the *duration* D_i is defined by $D_i = T_i - T_{i-1} \geq 0$, with the usual convention $T_0 = 0$, which explains the name *duration models*. The stopping time property is with respect to a given underlying filtration $(\mathcal{F}_t)_{t \geq 0}$. This filtration is supposed to model the information available to either the investigator (in order to perform inference) or an agent in a financial market (in order to take, e.g., investment decisions). Care is to be taken when extrapolating results on inference to actual financial market decisions if these information sets are different (where, often, the investigator's information set is smallest). Mathematically, the information structure is generally assumed to satisfy the so-called *usual conditions* [5].

The stopping-time property of T_i formally states that, for each $t \geq 0$, the event $\{T_i \leq t\}$ belongs to $\mathcal{F}_t$. As the filtration is, by definition, increasing ($\mathcal{F}_s \subset \mathcal{F}_t$ for $s \leq t$), we also have $\{T_i \leq s\} \in \mathcal{F}_t$ for $s \leq t$. Thus, informally, if T_i is a stopping time denoting the occurrence of an event then, at each time $t \geq 0$, we know whether the event has occurred already. Also, in case the event has occurred by time t , we know at which time $s \leq t$ it occurred.

Scale Models

A popular way to model the times T_i or, equivalently, the durations D_i is *via* a scale model. This method became popular in the financial econometrics literature because of its resemblance to volatility modeling (see, for instance, the *autoregressive conditional duration* (ACD) specification of [2]). In

these models, we write the i th duration as the product of two positive random variables, $D_i = \psi_i \varepsilon_i$. Here $(\varepsilon_i)_{i=1}^n$ is some *innovation sequence* and the properties of the model depend on the assumptions made on this innovation sequence. The scale factor ψ_i is assumed to be predetermined, meaning that ψ_i is measurable with respect to $\mathcal{F}_{T_{i-1}}$, the information available at time T_{i-1} . This information set allows the formalization of, for example, the expectation given the information at T_{i-1} and, in particular, leads to the *optional stopping theorem* [5]. Most of the literature identifies the scale of the innovation sequence by $E\{\varepsilon_i | \mathcal{F}_{T_{i-1}}\} = 1$. Such an assumption is innocuous insofar as the modeling is concerned, but may change the interpretation of parameters specifying ψ_i and thus inferential aspects as (semiparametric) adaptivity [1]. In the ACD specification, it is assumed that $\mathcal{F}_{T_i}$ is observed by the investigator, so that ψ_i is observed as well (up to unknown parameters). An alternative is given by the stochastic volatility duration (SVD) model of [3], where the expected duration ψ_i is modeled using an unobserved factor allowing for unobserved heterogeneity.

Point or Counting Process Models

In the probabilistic literature, point processes refer to stochastic processes that generate random points in a set [4]. Applied to the positive half line, this leads to models for random times/durations. As describing the location of certain points is equivalent to count the number of points in general sets, these processes are also called *counting processes*. The distributional properties of these processes are characterized by, for instance, the (conditional) *intensity measure*, which essentially gives the (conditionally) expected number of events in a small (time) interval.

Passage Time Models

A structural approach to duration models can be obtained, using as a duration the time it takes for a stochastic process to pass a certain threshold. In particular, if the underlying process is a Brownian motion this leads to Brownian hitting times, which are well studied. In this simplest setting, these hitting times (durations) are distributed according to the

inverse Gaussian distribution, which also explains the name for this distribution.

Proportional Hazard and Survival Models

Survival analysis is used in (bio)statistics to model uncertain lifetimes and can be adopted to model other (financial) durations. This literature uses, in particular, the *hazard* rate to model the duration of an event. The hazard rate is the (instantaneous) probability that the event will occur in the next time instance, given that it has not occurred so far. Mathematically, the hazard rate equals the density of the duration distribution, divided by its survival function (one minus the cumulative distribution function). In particular, the proportional hazard model has been used a lot. In such a model, predetermined variables multiply the baseline hazard, to give a conditional hazard.

Multivariate Models

In financial applications, there is much interest in jointly modeling several durations, for example, the transaction times for multiple assets. Owing to the nonsynchronous occurrence of events, this is a non-trivial exercise. In general, the point process approach is most suited in these circumstances, as the multivariate intensities can be modeled. Inference, though, is fairly involved.

Similarly, one is often interested in the joint behavior of durations and other quantities as volume or volatility. Such multivariate extensions can be complicated by possible subtle causality relations (both instantaneous and Granger) between the processes. Moment-based inference that takes these effects into account has been proposed in [6].

Mixed Data Sampling

Regression models that involve data sampled at different frequencies, or the so-called MIXED DATA Sampling (MIDAS) regression models, were introduced in both filtering and regression context in a number of recent papers, including [15, 17, 19], among others. These regressions deal with a situation often encountered in practice. For example, macroeconomic data are typically sampled at monthly or quarterly frequencies, whereas financial time series are sampled at almost any arbitrarily high frequency. Although most economic time series are not sampled at the same frequency, the typical practice of estimating econometric models involves aggregating all variables to the same (low) frequency using an equal weighting scheme.

Temporal aggregation in regression models, in contrast, is a well-studied area. The problem of temporal aggregation concerning dynamic models has been considered in the work of many authors, for example, [5, 11, 14, 21, 24, 26, 30–33, 36, 39–41].

In the first section, we draw comparisons between temporal aggregation and MIDAS. In the second section, we focus on a specific topic of special interest in finance–volatility forecasting.

Temporal Aggregation and MIDAS

MIDAS regressions not only share some features with distributed lag models but also have unique novel features. A stylized distributed lag model is a regression model of the following type: $y_t = \beta_0 + B(L)x_t + \varepsilon_t$, where $B(L)$ is some finite or infinite lag polynomial operator, usually parameterized by a small set of hyperparameters (see, e.g., [8] for a survey on distributed lag models). In a standard MIDAS regression model, the regressor is sampled m times more frequently than the regressand, where the latter has a sample of T observations. The asymptotics are based on T for a given m . Therefore, one studies the asymptotic properties of the estimators assuming that the span of the data set T grows and the high-frequency sample size of the regressors would be mT such that when $T \rightarrow \infty$ then both the low- and high-frequency samples tend to become large.

Andreou *et al.* [2] decompose the MIDAS regression model into two terms: the equal or flat aggregated term and a MIDAS term, which involves

weighted higher order differences of the high-frequency process. This decomposition allows one to link the MIDAS regression model with the traditional temporal aggregation literature, which omits the MIDAS term.

Consider the mixed data sampling data $\{y_t, \mathbf{x}_{t/m}^{(m)}\}$ where $\mathbf{x}_{t/m}^{(m)} = (1, x_{2,t/m}^{(m)}, \dots, x_{p,t/m}^{(m)})$ is a p -dimensional vector of higher frequency data observed at most m time between t and $t - 1$. The data are assumed to be weakly dependent. The conventional approach in empirical macroeconomics and finance employs the linear regression based on aggregated data, which are typically obtained by a pre-estimation procedure that computes simple averages to bring the high-frequency data to a common (low) frequency. In other words, the conventional approach employs the linear regression subject to the temporal aggregation restriction of an equal weighting scheme. Define the variable $\mathbf{x}_t^A = \frac{1}{m} \sum_{j=1}^m L^{j/m} \mathbf{x}_{t/m}^{(m)}$ that temporally aggregates the covariates $\mathbf{x}_{t/m}^{(m)}$ using equal weights (simple average), where q is the number of high-frequency lags used in the temporal aggregation of $\mathbf{x}_{t/m}^{(m)}$ with $L^{j/m}$ being the high-frequency lag operator. Then the conventional approach estimates by Least squares (LS) the following linear regression model:

$$y_t = \mathbf{x}_t^A \boldsymbol{\beta}^* + u_t^*, \quad q = 2, 3, \dots \quad (1)$$

where $E(u_t^* | \mathbf{x}_t^A) = 0$ and $E(u_t^{*2} | \mathbf{x}_t^A) = \sigma^{*2}$.

Consider now a projection of the high-frequency data onto y and let the linear polynomial of the projection be $\mathbf{W}(L^{1/m}; \boldsymbol{\theta})$, which is parameterized by a low-dimensional $r \times 1$ vector of parameters $\boldsymbol{\theta}$. Then we can define a MIDAS regression model as

$$y_t = \boldsymbol{\beta}' \mathbf{x}_t(\boldsymbol{\theta}) + u_t, \quad t = 1, 2, \dots, T \quad (2)$$

where $E(u_t | \mathbf{x}_{t/m}^{(m)}) = 0$ and $E(u_t^2 | \mathbf{x}_{t/m}^{(m)}) = \sigma^2$ where $\mathbf{x}_t(\boldsymbol{\theta}) = \left(1, x_{2,t}^{(m_2)}(\boldsymbol{\theta}_2), \dots, x_{p,t}^{(m_p)}(\boldsymbol{\theta}_p)\right)'$ is a nonlinear function that maps the higher frequency data into a common low frequency and

$$\begin{aligned} x_{k,t}^{(m)}(\boldsymbol{\theta}_k) &= W(L^{1/m}; \boldsymbol{\theta}_k) x_{k,t/h}^{(m)} \\ &= \sum_{j=1}^q w_{j,k}(\boldsymbol{\theta}_k) L^{j/m} x_{k,t/m}^{(m)}, \\ k &= 2, \dots, p \end{aligned} \quad (3)$$

where $w_{j,k}(\boldsymbol{\theta}_k) \in (0, 1)$ and $\sum_{j=1}^m w_{j,k}(\boldsymbol{\theta}_k) = 1$. The latter assumption allows the identification of the slope

coefficient vector β . Equation (2) is a nonlinear regression that allows both the weighting scheme of the temporal aggregation as parameterized by the vector θ and the slope coefficient vector β to be estimated from the data. Following Ghysels *et al.* [17] the lag coefficients, $w_{j,k}(\theta_k)$, which determine the weighting scheme used, are parsimoniously parameterized *via* exponential Almon, Almon, Beta, or step function schemes.

Andreou *et al.* [2] study regression models that involve data sampled at different frequencies and compare them with a traditional model that involves temporal aggregation for the estimation of a model at the same sampling frequency that implies an equal weighting scheme. They derive the asymptotic properties of the MIDAS nonlinear least squares (MIDAS-NLS) estimators of regression models with mixed frequencies and general weighting schemes and show that the LS estimator is always relatively less efficient than the MIDAS-NLS estimator. Our analysis reveals the effects of the aggregation horizon on the properties of the MIDAS-NLS and temporally aggregated or FLAT-LS estimators. In particular, they show that the FLAT-LS estimator is asymptotically biased and inefficient when the high-frequency regressor exhibits linear temporal dependence as in the case of AR(1), while it is only inefficient in the case of *i.i.d.* and ARCH(1) high-frequency processes. Furthermore, they propose two types of aggregation bias tests: a simple LM test and a Wu–Hausman-type test that uses the high-frequency variables as instruments.

To conclude, it is worth discussing one particular application of regression models, namely, testing for Granger causality among variables—a topic of interest in many financial applications. Much has been written about the spurious effects temporal aggregation may have on testing for Granger causality; see, for example [4, 20, 22, 23, 27, 28, 34], among others. Ghysels and Valkanov [18] show that there are unexplored advantages in testing Granger causality in combining the data sampled at the different frequencies. They develop a set of Granger causality tests that explicitly take advantage of data sampled at different frequencies. Along similar lines, Andreou *et al.* (2009) document many predictable patterns between daily financial data and monthly and quarterly macroeconomic variables. Such patterns significantly improve macroeconomic forecasts. Recent work on this topic includes improving quarterly macroforecasts with

monthly data using MIDAS regressions [3, 7, 13, 35, 38] or improving quarterly and monthly macroeconomic predictions with daily financial data [2]; Ghysels and Wright (2008); [25, 37].

Volatility Forecasting with MIDAS

The original work on MIDAS focused on volatility predictions [1, 6, 10, 12, 15, 16], among others. The abundance of high-frequency data, combined with the desire to predict volatility over longer horizons, provides an ideal setting for applying such regressions. The original work on MIDAS was in fact a filtering and not a regression setting. Ghysels *et al.* [15] studied the risk-return trade-off—where returns were computed over longer horizons, whereas risk was measured by conditional variance over the same horizon but measured with a filter of weighted daily returns. In [16], the same approach was adopted in a regression format to predict multihorizon volatility. Chen and Ghysels [6] take this a step further and use a semiparametric MIDAS regression that related news impact curves applied to intradaily data to future realized volatility. They find that returns have significant asymmetric effects on future volatility—a topic somehow lost in the recent realized volatility literature—as originally emphasized in the context of ARCH-type models by Engle and Ng (1993). As mentioned in the previous section, this work distinguishes itself from the more standard temporal aggregation literature in the context of volatility [9, 29].

ERIC GHYSELS

Pricing Kernels

Pricing kernels or stochastic discount factors (SDFs) (see **Stochastic Discount Factors**) are used to represent valuation operators in dynamic stochastic economies. A kernel is a commonly used mathematical term for representing an operator. The term *stochastic discount factor (SDF)* extends concepts from economics and finance to include adjustments for risk. As we will see, there is a close connection between the two terms. The terms *pricing kernel* and SDF are often used interchangeably.

After deriving convenient representations for prices, we provide several examples of stochastic discount factors and discuss econometric methods for estimating and testing asset pricing models that restrict stochastic discount factors.

Representing Prices

We follow Ross [49] and Harrison and Kreps [34] by exploring the implications of no arbitrage in frictionless markets to obtain convenient representations of pricing operators. We build these operators as mappings that assign prices that trade in competitive markets to payoffs on portfolios of assets. The payoffs specify how much a numeraire good is provided in alternative states of the world. To write these operators, we invoke the *law of one price*, which stipulates that any two assets with the same payoff must necessarily have the same price. This law is typically implied by but is weaker than the *principle of no arbitrage* (see **Fundamental Theorem of Asset Pricing**). Formally, the principle of no arbitrage stipulates that nonnegative payoffs that are positive with positive (conditional) probability command a strictly positive price. To see why the principle implies the law of one price, suppose that there is such a nonnegative portfolio payoff and call this portfolio a . If two portfolios, say b and c have the same payoff but the price of portfolio b is less than that of portfolio c , then an arbitrage opportunity exists. This can be seen by taking a long position on portfolio b , a short position on portfolio c , and using the proceeds to purchase portfolio a . This newly constructed portfolio has zero price but a positive payoff, violating the principle of no arbitrage.

Given that we can assign prices to payoffs, let $\pi_{t,t+1}$ be the date t valuation operator for payoffs (consumption claims) at date $t + 1$. This operator assigns prices or values to portfolio payoffs p_{t+1} in a space P_{t+1} suitably restricted. We extend Debreu's [17] notion of a valuation functional to a valuation operator to allow for portfolio prices to depend on date t information. With this in mind, let $\mathcal{F}_t$ be the sigma algebra used to depict the information available to all investors at date t . We use a representation of $\pi_{t,t+1}$ of the following form:

$$\pi_{t,t+1}(p_{t+1}) = E(s_{t+1}p_{t+1}|\mathcal{F}_t) \quad (1)$$

for some positive random variable s_{t+1} with probability one and any admissible payoff $p_{t+1} \in P_{t+1}$ on a portfolio of assets.

Definition 1 *The positive random variable s_{t+1} is the pricing kernel of the valuation operator $\pi_{t,t+1}$, provided that representation (1) is valid.*

If a kernel representation exists, the valuation operator $\pi_{t,t+1}$ necessarily satisfies the principle of no arbitrage.

How does one construct a representation of this type? There are alternative ways to achieve this. First, suppose that (i) P_{t+1} consists of all random variables that are $\mathcal{F}_{t+1}$ measurable and have finite conditional (on $\mathcal{F}_t$) second moments, (ii) $\pi_{t,t+1}$ is linear conditioned on $\mathcal{F}_t$, (iii) $\pi_{t,t+1}$ also satisfies a conditional continuity restriction, and (iv) the principle of no arbitrage is satisfied. The existence of a kernel s_{t+1} follows from a conditional version of the Riesz representation theorem [30]. Second, suppose that (i) P_{t+1} consists of all bounded random variables that are $\mathcal{F}_{t+1}$ measurable, (ii) $\pi_{t,t+1}$ is linear conditioned on $\mathcal{F}_t$, (iii) $E(\pi_{t,t+1})$ induces an absolutely continuous measure on $\mathcal{F}_{t+1}$, and (iv) the principle of no arbitrage is satisfied. We can apply the Radon–Nikodym theorem to justify the existence of a kernel. In both these cases, security markets are *complete* in that payoffs of any indicator function for events in $\mathcal{F}_{t+1}$ are included in the domain of the operator.^a Kernels can be constructed for other mathematical restrictions on asset payoffs and prices as well.

As featured by Harrison and Kreps [34] and Hansen and Richard [30], suppose that P_t is not so richly specified. Under the (conditional) Hilbert space formulation and appropriate restrictions on P_t , we may still apply a (conditional) version of the Riesz

representation theorem to represent

$$\pi_{t,t+1}(p_{t+1}) = E(q_{t+1} p_{t+1} | \mathcal{F}_t) \quad (2)$$

for some $q_{t+1} \in P_{t+1}$ and all $p_{t+1} \in P_{t+1}$. Even if the principle of no arbitrage is satisfied, there is no guarantee that the resulting q_{t+1} is positive with probability 1, however. Provided, however, that we can extend P_{t+1} to a larger space that includes indicator functions for events in $\mathcal{F}_{t+1}$ while preserving the principle of no arbitrage, when there exists a pricing kernel s_{t+1} for $\pi_{t,t+1}$. However, the pricing kernel may not be unique.

Stochastic Discounting

The random variable s_{t+1} is also called the *one-period stochastic discount factor*. Its multiperiod counterpart is as follows.

Definition 2 The stochastic discount process $\{S_{t+1} : t = 1, 2, \dots\}$ is

$$S_{t+1} = \prod_{j=1}^{t+1} s_j \quad (3)$$

where s_j is the pricing kernel used to represent the valuation operator between dates $j-1$ and j .

Thus, the $t+1$ period SDF compounds the corresponding one-period SDFs. The compounding is justified by the law of iterated values when trading is allowed at intermediate dates. As a consequence,

$$\pi_{0,t+1}(p_{t+1}) = E(S_{t+1} p_{t+1} | \mathcal{F}_0) \quad (4)$$

gives the date zero price of a security that pays p_{t+1} in the numeraire at date $t+1$. An SDF discounts the future in a manner that depends on future outcomes. This outcome dependence is included in order to make adjustments for risk. However, such adjustments are unnecessary for a discount bond because such a bond has a payoff that is equal to one independent of the state realized at date $t+1$. The price of a date $t+1$ discount bond is obtained from formula (4) by letting $p_{t+1} = 1$ and hence is given by $E[S_{t+1} | \mathcal{F}_0]$.

More generally, the date τ price of p_{t+1} is given as

$$\pi_{\tau,t+1}(p_{t+1}) = E\left[\left(\frac{S_{t+1}}{S_\tau}\right) p_{t+1} | \mathcal{F}_\tau\right] \quad (5)$$

for $\tau \leq t$. Thus, the ratio $\frac{S_{t+1}}{S_\tau}$ is the pricing kernel for the valuation operator $\pi_{\tau,t+1}$.

Risk-neutral Probabilities

Given a one-period pricing kernel, we build the so-called *risk-neutral probability measure* recursively as follows. First, rewrite the one-period pricing operator as

$$\pi_{t,t+1}(p_{t+1}) = E(s_{t+1} | \mathcal{F}_t) \tilde{E}(p_{t+1} | \mathcal{F}_t) \quad (6)$$

where

$$\tilde{E}(p_{t+1} | \mathcal{F}_t) = E\left[\left(\frac{s_{t+1}}{E(s_{t+1} | \mathcal{F}_t)}\right) p_{t+1} | \mathcal{F}_t\right] \quad (7)$$

Thus, one-period pricing is conveniently summarized by a one-period discount factor for a riskless payoff, $E(s_{t+1} | \mathcal{F}_t)$, and a change of the conditional probability measure implied by the conditional expectation operator $\tilde{E}(\cdot | \mathcal{F}_t)$. Risk adjustments are now absorbed into the change of probability measure.

Using this construction repeatedly, we decompose the date $t+1$ component of the SDF process:

$$S_{t+1} = \bar{S}_{t+1} M_{t+1} \quad (8)$$

where

$$\bar{S}_{t+1} = \left[\prod_{j=1}^{t+1} E(s_j | \mathcal{F}_{j-1}) \right] \quad (9)$$

is the discount factor constructed from the sequence of one-period riskless discount factors and

$$M_{t+1} = \prod_{j=1}^{t+1} \frac{s_j}{E(s_j | \mathcal{F}_{j-1})} = \frac{S_{t+1}}{\bar{S}_{t+1}} \quad (10)$$

is the positive martingale adapted to $\{\mathcal{F}_t : t = 0, 1, \dots\}$ with expectation unity. For each date t , M_t can be used to assign probabilities to events in $\mathcal{F}_t$. Since $E(M_{t+1} | \mathcal{F}_t) = M_t$, the date $t+1$ assignment of probabilities to events in $\mathcal{F}_{t+1}$ is compatible with the date t assignment to events in $\mathcal{F}_t \subset \mathcal{F}_{t+1}$. This follows from the law of iterated expectations. In effect, the law of iterated expectations enforces the law of iterated values.

Applying factorization (8), we have an alternative way to represent $\pi_{\tau,t+1}$:

$$\pi_{\tau,t+1}(p_{t+1}) = \tilde{E}[\bar{S}_{t+1} p_{t+1} | \mathcal{F}_\tau] \quad (11)$$

Pricing is reduced to riskless discounting and a distorted (risk-neutral) conditional expectation. The insight provided in [34, 49] is that dynamic asset pricing in the absence of arbitrage is captured by the existence of a positive (with probability one) martingale that can be used to represent prices in conjunction with a sequence of one-period riskless discount factors. Moreover, it justifies an arguably mild modification of the “efficient market hypothesis” that states that discounted prices should behave as martingales with the appropriate cash-flow adjustment. While Rubinstein [50] and Lucas [42] had clearly shown that efficiency should not preclude risk compensation, the notion of equivalent martingale measures reconciles the points of view under greater generality. The martingale property and associated “risk-neutral pricing” are recovered for some distortion of the historical probability measure that encapsulates risk compensation. This distortion preserves “equivalence” (the two probability measures agree about which events in $\mathcal{F}_t$ are assigned probability zero measure for each finite t) by ensuring the existence of a strictly positive SDF.

The concept of equivalent martingale measure (for each t) has been tremendously influential in derivative asset pricing. The existence of such a measure allows risk-neutral pricing of all contingent claims that are attainable because their payoff can be perfectly duplicated by self-financing strategies. Basic results from probability theory are directly exploitable in characterizing asset pricing in an arbitrage-free environment. More details can be found in **Econometrics of Option Pricing**.

Although we have developed this discussion for a discrete-time environment, there are well-known continuous-time extensions. In the case of continuous-time Brownian motion information structures, the change of measure has a particularly simple structure. In accordance to the Girsanov theorem, the Brownian motion under the original probability measure becomes a Brownian motion with drift under the risk-neutral measure. These drifts absorb the adjustments for exposure to Brownian motion risk.

Investors’ Preferences

Economic models show how exposure to risk is priced and what determines riskless rates of interest. As featured by Ross [49], the risk exposure that

is priced is the risk that cannot be diversified by averaging through the construction of portfolios of traded securities. Typical examples include macroeconomic shocks. Empirical macroeconomics seeks to identify macroeconomic shocks to quantify responses of macroeconomic aggregates to those shocks. Asset pricing models assign prices to exposure of cash flows to the identified shocks. The risk prices are encoded in SDF processes and hence are implicit in the risk-neutral probability measures used in financial engineering.

SDFs implied by specific economic models often reflect investor preferences. Subjective rates of discount and intertemporal elasticities appear in formulas for risk-free interest rates, and investors’ aversion to risk appears in formulas for the prices assigned to alternative risk exposures. Sometimes the reflection of investor preferences is direct and sometimes it is altered by the presence of market frictions. In what follows, we illustrate briefly some of the SDFs that have been derived in the literature.

Power Utility

When there are no market frictions and markets are complete, investors’ preferences can be subsumed into a utility function of a representative agent. In what follows, suppose that the representative investor has discounted time-separable utility with a constant elasticity of substitution (CES) $1/\rho$:

$$\frac{S_{t+1}}{S_t} = \exp(-\delta) \left(\frac{C_{t+1}}{C_t} \right)^{-\rho} \quad (12)$$

This is the SDF for the power utility specification of the model of Rubinstein [50] and Lucas [42].^b

Recursive Utility

Following Epstein and Zin [18], Kreps and Porteus [41] and Weil [53], preferences are specified recursively using continuation values for hypothetical consumption processes. Using a double CES recursion, the resulting SDF is

$$\frac{S_{t+1}}{S_t} = \exp(-\delta) \left(\frac{C_{t+1}}{C_t} \right)^{-\rho} \left[\frac{U_{t+1}}{R_t(U_{t+1})} \right]^{\rho-\gamma} \quad (13)$$

where $\gamma > 0$, $\rho > 0$, U_t is the continuation value associated with current and future consumption, and

$$R_t(U_{t+1}) \doteq (E[(U_{t+1})^{1-\gamma} | \mathcal{F}_t])^{1/(1-\gamma)} \quad (14)$$

is the risk-adjusted continuation value. The parameter ρ continues to govern the elasticity of substitution, whereas the parameter γ alters the risk preferences. See [25, 31, 52] for a discussion of the use of continuation values in representing the SDF and see [11, 25] for discussions of empirical implications. When $\rho = 1$, the recursive utility model coincides with a model in which investors have a concern about robustness as in [6].

The recursive utility model is just one of a variety of ways of altering investors' preferences. For instance, Constantinides [15] and Heaton [36] explore implications of introducing intertemporal complementarities in the form of "habit persistence".

Consumption Externalities and Reference Utility

Abel [1], Campbell and Cochrane [12] and Menzly *et al.* [45] develop asset pricing implications of models in which there are consumption externalities in models with stochastic consumption growth. These externalities can depend on a social stock of past consumptions. The implied one-period SDF in these models has the following form:

$$\frac{S_{t+1}}{S_t} = \exp(-\delta) \left(\frac{C_{t+1}}{C_t} \right)^{-\rho} \frac{\phi(H_t)}{\phi(H_0)} \quad (15)$$

The social stock of consumption is built as a possibly nonlinear function of current and past social consumption or innovations to social consumption. The construction of this stock differs across the various specifications. The process $\{H_t : t = 0, 1, \dots\}$ is the ratio of the consumption to the social stock and ϕ is an appropriately specified function of this ratio. In a related approach, Garcia *et al.* [21] consider investors' preferences in consumption as being evaluated relative to a reference level that is determined externally. The SDF is

$$\frac{S_{t+1}}{S_t} = \exp(-\delta) \left(\frac{C_{t+1}}{C_t} \right)^{-\rho} \left(\frac{H_t}{H_0} \right)^\eta \quad (16)$$

where the process $\{H_t : t = 0, 1, \dots\}$ is the ratio of the consumption to the reference level. In effect, the social externality in these models induces a preference shock or wedge to the SDF specification, which explicitly depends on the equilibrium aggregate consumption process. Finally, Bakshi and Chen [8] develop implications for a model in which relative wealth enters the utility function of investors.

Incomplete Markets

Suppose that individuals face private shocks that they cannot insure against but that they can write complete contracts over aggregate shocks. Let $\mathcal{F}_{t+1}$ denote the date $t + 1$ sigma algebra generated by aggregate shocks available up until date $t + 1$. This conditioning information set determines the type of risk exposure that can be traded as of date $t + 1$. Under this partial risk sharing and power utility, the SDF for pricing aggregate uncertainty is

$$\begin{aligned} \frac{S_{t+1}}{S_t} &= \exp(-\delta) \left(\frac{E[(C_{t+1}^j)^{-\rho} | \mathcal{F}_{t+1}]}{E[(C_t^j)^{-\rho} | \mathcal{F}_t]} \right) \\ &= \exp(-\delta) \left(\frac{C_{t+1}^a}{C_t^a} \right)^{-\rho} \\ &\quad \times \left(\frac{E[(C_{t+1}^j / C_{t+1}^a)^{-\rho} | \mathcal{F}_{t+1}]}{E[(C_t^j / C_t^a)^{-\rho} | \mathcal{F}_t]} \right) \end{aligned} \quad (17)$$

In this example and those that follow, C_{t+1}^j is consumption for individual j and C_{t+1}^a is aggregate consumption. Characterization (17) of the SDF displays the pricing implications of limited risk sharing in security markets. It is satisfied, for instance, in the model of Constantinides and Duffie [16].

Private Information

Suppose that individuals have private information about labor productivity that is conditionally independent, given aggregate information, leisure enters preferences in a manner that is additively separable and consumption allocations are Pareto optimal given the private information. As shown by Kocherlakota and Pistaferri [40], the SDF follows from the "inverse Euler equation" of [40, 47],

$$\begin{aligned} \frac{S_{t+1}}{S_t} &= \exp(-\delta) \left(\frac{E[(C_t^j)^\rho | \mathcal{F}_t]}{E[(C_{t+1}^j)^\rho | \mathcal{F}_{t+1}]} \right) \\ &= \exp(-\delta) \left(\frac{C_{t+1}^a}{C_t^a} \right)^{-\rho} \\ &\quad \times \left(\frac{E[(C_t^j / C_t^a)^\rho | \mathcal{F}_t]}{E[(C_{t+1}^j / C_{t+1}^a)^\rho | \mathcal{F}_{t+1}]} \right) \end{aligned} \quad (18)$$

where $\mathcal{F}_t$ is generated by the public information. As emphasized by Rogerson [47], this is a model with a form of “savings constraints”. While the stochastic discount factor for the incomplete information model is expressed in terms of the $(-\rho)^{\text{th}}$ moments of the cross-sectional distributions of consumption in adjacent time periods Kocherlakota and Pistaferri [40] show that in the private information model it is the ρ th moments of these same distributions.

Solvency Constraints

Luttmer [43], He and Modest [35], and Cochrane and Hansen [14] study asset pricing implications in models with limits imposed on the state contingent debt that is allowed. Alvarez and Jermann [4] motivate such constraints by appealing to limited commitment as in [38, 39]. When investors default, they are punished by excluding participation in asset markets in the future. Chien and Lustig [13] explore the consequences of alternative (out of equilibrium) punishments. Following [43], the SDF in the presence of solvency constraints and power utility is

$$\frac{S_{t+1}}{S_t} = \exp(-\delta) \left(\min_j \frac{C_{t+1}^j}{C_t^j} \right)^{-\rho} \quad (19)$$

and in particular,

$$\frac{S_{t+1}}{S_t} \geq \exp(-\delta) \left(\frac{C_{t+1}^a}{C_t^a} \right)^{-\rho} \quad (20)$$

Thus, the consumer with the smallest realized growth rate in consumption has a zero Lagrange multiplier on his or her solvency constraint, and hence the intertemporal marginal rate of substitution for this person is equal to the SDF. For the other consumers, the binding constraint prevents them shifting consumption from the future to the current period.

Long-term Risk

The SDF process assigns prices to risk exposures at alternative investment horizons. To study pricing over these horizons, Alvarez and Jermann [5], Hansen and Scheinkman [32], and Hansen [24] use a Markov structure and apply factorizations of the following form:

$$S_{t+1} = \exp(-\eta t) M_{t+1} \frac{\hat{f}(X_0)}{\hat{f}(X_{t+1})} \quad (21)$$

where $\{M_t : t = 0, 1, \dots\}$ is a *multiplicative martingale*, η is a positive number, $\{X_t : t = 0, 1, \dots\}$ is an underlying Markov process, and $\hat{f}$ is a positive function of the Markov state. The martingale is used as a convenient change of probability, one that is distinct from the “risk-neutral” measure described previously. Using this change of measure, asset prices can be depicted as

$$\pi_{0,t+1}(p_{t+1}) = \exp[-\eta(t+1)] \times \hat{E} \left[\frac{p_{t+1}}{\hat{f}(X_{t+1})} | X_0 \right] \hat{f}(X_0) \quad (22)$$

where $\hat{E}$ is the conditional expectation that is built with the martingale $\{M_t : t \geq 0\}$ in (21). The additional discounting is now constant and simple expectations can now be computed by exploiting the Markov structure. Hansen and Scheinkman [32] give necessary and sufficient conditions for the martingale in factorization (21) to imply a change of probability measure with stable stochastic dynamics.^c While Alvarez and Jermann [5] use this factorization to investigate the long-term links between the bond market and the macroeconomy, Hansen and Scheinkman [32] and Hansen [24] extend this factorization to study the valuation of cash flows that grow stochastically over time. As argued by Hansen and Scheinkman [32] and Hansen [24], these more general factorizations are valuable for the study of risk-return trade-offs for long investment horizons.

As argued by Bansal and Lehmann [9], many alterations to the power utility model in the section Power Utility can be represented as

$$\frac{S_{t+1}^*}{S_t^*} = \left(\frac{S_{t+1}}{S_t} \right) \left[\frac{f(X_{t+1})}{f(X_t)} \right] \quad (23)$$

for a positive function f . Transient components in asset pricing models are included to produce short-term alterations in asset prices and are expressed as the ratio of a function of the Markov state in adjacent dates. As shown by Bansal and Lehmann [9], this representation arises in models with habit persistence, or as shown in [24] the same is true for a limiting version of the recursive utility model. Combining equation (23) with equation (21) gives

$$S_{t+1}^* = \exp(-\eta) M_{t+1} \frac{f^*(X_0)}{f^*(X_{t+1})} \quad (24)$$

where $f^* = \hat{f}/f$.

Inferring Stochastic Discount Factors from Data

Typically a finite number of asset payoffs are used in econometric practice. In addition, the information used in an econometric investigation may be less than that used by investors. With this in mind, let Y_{t+1} denote an n -dimensional vector of asset payoffs observed by the econometrician such that

$$E(|Y_{t+1}|^2|\mathcal{G}_t) < \infty \quad (25)$$

with $E(Y_{t+1}Y_{t+1}'|\mathcal{G}_t)$ nonsingular with probability 1 and $\mathcal{G}_t \subset \mathcal{F}_t$. Let Q_t denote the corresponding price vector that is measurable with respect to $\mathcal{G}_t$, implying that

$$E(s_{t+1}Y_{t+1}|\mathcal{G}_t) = Q_t \quad (26)$$

where $s_{t+1} = S_{t+1}/S_t$. We may construct a counterpart to a (one-period) SDF by forming

$$p_{t+1}^* = Y_{t+1}' [E(Y_{t+1}Y_{t+1}'|\mathcal{G}_t)]^{-1} Q_t \quad (27)$$

Note that

$$E(p_{t+1}^* Y_{t+1} | \mathcal{G}_t) = Q_t \quad (28)$$

suggesting that we could just replace s_{t+1} in equation (26) with p_{t+1}^* . We refer to p_{t+1}^* as a *counterpart* to an SDF because we have not restricted p_{t+1}^* to be positive.

This construction is a special case of the representation of the prices implied by a conditional version of the Riesz representation theorem [30]. Since p_{t+1}^* is not guaranteed to be positive, if we used it to assign prices to derivative claims (nonlinear functions of Y_{t+1}), we might induce arbitrage opportunities. Nevertheless, provided that s_{t+1} has a finite conditional second moment,

$$E[(s_{t+1} - p_{t+1}^*) Y_{t+1} | \mathcal{G}_t] = 0 \quad (29)$$

This orthogonality indicates that p_{t+1}^* is the conditional least-squares projection of s_{t+1} onto Y_{t+1} . Although a limited set of asset price data will not reveal s_{t+1} , the data can provide information about the date $t+1$ kernel for pricing over a unit time interval.

Suppose that Y_{t+1} contains a conditionally riskless payoff. Then

$$E(s_{t+1}|\mathcal{G}_t) = E(p_{t+1}^*|\mathcal{G}_t) \quad (30)$$

By a standard least-squares argument, the conditional volatility of s_{t+1} must be at least as large as the conditional volatility of p_{t+1}^* . There are a variety of other restrictions that can be derived. For instance, see [9, 28, 51].^d

This construction has a direct extension to the case in which a complete set of contracts can be written over the derivative claims. Let H_{t+1} be the set of all payoffs that have finite second moments conditioned on $\mathcal{G}_t$ and are of the form $h_{t+1} = \phi(Y_{t+1})$ for some Borel measurable function ϕ . Then, we may obtain a kernel representation for pricing claims with payoffs in H_{t+1} by applying the Riesz representation theorem:

$$\pi_t(h_{t+1}) = E(h_{t+1}^* h_{t+1} | \mathcal{G}_t) \quad (31)$$

for some h_{t+1}^* in H_{t+1} . Then

$$E[(s_{t+1} - h_{t+1}^*) h_{t+1} | \mathcal{G}_t] = 0 \quad (32)$$

which shows that the conditional least-squares projection of s_{t+1} onto H_{t+1} is h_{t+1}^* . In this case, h_{t+1}^* will be positive. Thus, this richer collection of observed tradable assets implies a more refined characterization of s_{t+1} including the possibility that $s_{t+1} = h_{t+1}^*$, provided H_{t+1} coincides with the full collection of one-period payoffs that could be traded by investors. The estimation procedures of [3, 48] can be interpreted as estimating h_{t+1}^* projected on the return information.

Linear Asset Pricing Models

The long history of linear beta pricing can be fruitfully revisited within the SDF framework. Suppose that

$$Q_t = E[(\lambda_t \cdot z_{t+1} + \alpha_t) Y_{t+1} | \mathcal{G}_t] \quad (33)$$

for some vector λ_t and some scalar α_t that are $\mathcal{G}_t$ measurable. Then

$$E[Y_{t+1} | \mathcal{G}_t] = \alpha_t^* Q_t + \lambda_t^* \cdot \text{cov}(Y_{t+1}, z_{t+1} | \mathcal{G}_t) \quad (34)$$

where

$$\begin{aligned} \alpha_t^* &= \frac{1}{\alpha_t + \lambda_t \cdot E(z_{t+1} | \mathcal{G}_t)} \\ \lambda_t^* &= -\lambda_t \alpha_t^* \end{aligned} \quad (35)$$

which produces the familiar result that risk compensation expressed in terms of the conditional mean discrepancy: $E[Y_{t+1}|\mathcal{G}_t] - \alpha_t^* Q_t$ depends on the conditional covariances with the factors. When the entries of z_{t+1} are standardized to have conditional variances equal to unity, the entries of λ_t^* become the conditional regression coefficients, the “betas” of the asset payoffs onto the alternative observable factors. When z_{t+1} is the scalar market return, this specification gives the familiar CAPM from empirical finance. When z_{t+1} is augmented to include the payoff on a portfolio designed to capture risk associated with size (market capitalization) and the payoff on a portfolio designed to capture risk associated with book to market equity, this linear specification gives a conditional version of the [19] three-factor model designed to explain cross-sectional differences in expected returns (see **Factor Models**).

If the factors are among the asset payoffs and a conditional (on $\mathcal{G}_t$) riskless payoff is included in Y_{t+1} , then

$$p_{t+1}^* = \lambda_t \cdot z_{t+1} + \alpha_t \quad (36)$$

and thus $\lambda_t \cdot z_{t+1} + \alpha_t$ is the conditional least-squares regression of s_{t+1} onto Y_{t+1} .

For estimation and inference, consider the special case in which $\mathcal{G}_t$ is degenerate and the vector Y_{t+1} consists of excess returns (Q_t is a vector of zeros). Suppose that the data generation process for $\{(z_{t+1}, Y_{t+1})\}$ is independent and identically distributed (i.i.d.) and multivariate normal. Then α_t and λ_t are time invariant. The coefficient vectors can be efficiently estimated by maximum likelihood and the pricing restrictions tested by likelihood ratio statistics [22]. As MacKinlay and Richardson [44] point out, it is important to relax the i.i.d. normal assumption in many applications. In contrast with the parametric maximum likelihood approach, generalized method of moments (GMM) provides an econometric framework that allows conditional heteroskedasticity and temporal dependence [23]. Moreover, the GMM approach offers the important advantage to provide a unified framework for the testing of conditional linear beta pricing models. See [37] for an extensive discussion of the application of GMM to linear factor models. We will have more to say about estimation when $\mathcal{G}_t$ is not degenerate in our subsequent discussion.

Suppose that the conditional linear pricing model is misspecified. Hansen and Jagannathan [29] show

that choosing (λ_t, α_t) to minimize the maximum pricing error of payoffs with $E(|p_{t+1}|^2|\mathcal{G}_t) = 1$ is equivalent to solving the least-squares problem:^e

$$\begin{aligned} \min_{\lambda_t, \alpha_t, v_{t+1}, E((v_{t+1})^2|\mathcal{G}_t) < \infty} & E[(\lambda_t \cdot z_{t+1} + \alpha_t - v_{t+1})^2|\mathcal{G}_t] \\ \text{subject to } & Q_t = E(v_{t+1} Y_{t+1}|\mathcal{G}_t) \end{aligned} \quad (37)$$

This latter problem finds a random variable v_{t+1} that is close to $\lambda_t \cdot z_{t+1} + \alpha_t$, allowing for departures from pricing formula (33) where v_{t+1} is required to represent prices correctly. For a fixed (λ_t, α_t) , the “concentrated” objective is

$$\begin{aligned} & [E[\lambda_t \cdot z_{t+1} + \alpha_t] Y_{t+1}|\mathcal{G}_t] - Q_t]' \\ & \times [E(Y_{t+1} Y_{t+1}'|\mathcal{G}_t)]^{-1} \\ & \times [E[\lambda_t \cdot z_{t+1} + \alpha_t] Y_{t+1}|\mathcal{G}_t] - Q_t] \end{aligned} \quad (38)$$

which is a quadratic form of the vector of pricing error. The random vector (λ_t, α_t) is chosen to minimize this pricing error. In the case of a correct specification, this minimization results in a zero objective; otherwise, it provides a measure of model misspecification.

Estimating Parametric Models

In examples of SDFs like those given in the section Investors’ Preferences, there are typically unknown parameters to estimate. This parametric structure often permits the identification of the SDF even with limited data on security market payoffs and prices. To explore this approach, we introduce a parameter θ that governs say investors’ preferences. It is worth noting that inference about θ is a semiparametric statistical problem since we avoid the specification of the law of motion of asset payoffs and prices along with the determinants of SDFs. In what follows, we sketch the main statistical issues in the following simplified context.

Suppose that $s_{t+1} = \phi_{t+1}(\theta_o)$ is a parameterized model of an SDF that satisfies

$$E[\phi_{t+1}(\theta_o) Y_{t+1}|\mathcal{G}_t] - Q_t = 0 \quad (39)$$

where ϕ_{t+1} can depend on observed data but the parameter vector θ_o is unknown. This conditional

moment restriction implies a corresponding unconditional moment condition:

$$E[\phi_{t+1}(\theta_o)Y_{t+1} - Q_t] = 0 \quad (40)$$

As emphasized by Hansen and Richard [30], conditioning information can be brought in through the back door by scaling payoffs and their corresponding prices by random variables that are $\mathcal{G}_t$ measurable. Hansen and Singleton [33] describe how to use the unconditional moment condition to construct a GMM estimator of the parameter vector θ_o with properties characterized by Hansen [23] (see also **Generalized Method of Moments (GMM)**).

As an alternative, the parameterized family of models might be misspecified. Then the approach of [29] described previously could be used, whereby an estimator of θ_o is obtained by minimizing

$$\left[\frac{1}{N} \sum_{t=1}^N \phi_{t+1}(\theta) Y_{t+1} - Q_t \right] \left[\frac{1}{N} \sum_{t=1}^N Y_{t+1} Y_{t+1}' \right]^{-1} \times \left[\frac{1}{N} \sum_{t=1}^N \phi_{t+1}(\theta) Y_{t+1} - Q_t \right] \quad (41)$$

with respect to θ . This differs from a GMM formulation because the weighting matrix in the quadratic form does not depend on the SDF, but only on the second moment matrix of the payoff vector Y_{t+1} . This approach suffers from a loss of statistical efficiency in estimation when the model is correctly specified, but it facilitates comparisons across models because the choice of an SDF does not alter how the overall magnitude of the pricing errors is measured.

As in [26, 29], the analysis can be modified to incorporate the restriction that pricing errors should also be small for payoffs on derivative claims. This can be formalized by computing the time series approximation to the least-squares distance between a candidate, but perhaps misspecified, SDF from the family of strictly positive random variables z_{t+1} that solve the pricing restriction:

$$E(z_{t+1}Y_{t+1} - Q_t) = 0 \quad (42)$$

See [25] for more discussion of these alternative approaches for estimation.

So far we have described econometric methods that reduce conditional moment restrictions (33) and (40)

to their unconditional counterparts. From a statistical perspective, it is more challenging to work with the original conditional moment restriction. Along this vein, Ai and Chen [2] and Antoine *et al.* [7] develop nonparametric methods to estimate conditional moment restrictions used to represent pricing restrictions. In particular, Antoine *et al.* [7] develop a conditional counterpart to the continuously updated GMM estimator introduced by Hansen *et al.* [27] in which the weighting matrix in GMM objective explicitly depends on the unknown parameter to be estimated.^f These same methods can be adapted to explicitly take account of conditioning information while allowing for misspecification as in [29].

Acknowledgment

Jarda Borovicka provided suggestions that were very helpful for this article.

End Notes

^aSee [46] for a dynamic extension using this approach.

^bSee [10] for a continuous-time counterpart.

^cAlthough Hansen and Scheinkman [32] use a continuous-time formulation, discrete-time counterparts to their analysis are straightforward to obtain.

^dThese authors do not explicitly use conditioning information. In contrast, Gallant *et al.* [20] estimate conditional moment restrictions using a flexible parameterization for the dynamic evolution of the data.

^eHansen and Jagannathan [29] abstract from conditioning information, but what follows is a straightforward extension.

^fThe continuously updated estimator is also closely related to the “minimum entropy” and “empirical likelihood” approaches (see **Entropy-based Estimation**).

Entropy-based Estimation

Let P, μ be two probability measures on a probability space, with P absolutely continuous with respect to μ (see **Equivalence of Probability Measures**), and denote the density of P with respect to μ by $dP/d\mu > 0$. The *relative entropy* $D(P\|\mu)$, sometimes called the *Kullback–Leibler information* [9] or divergence in statistics, is defined as

$$\begin{aligned} D(P\|\mu) &= \int_{\Omega} \log\left(\frac{dP}{d\mu}\right) dP \\ &= \int_{\Omega} \frac{dP}{d\mu} \log\left(\frac{dP}{d\mu}\right) d\mu \end{aligned} \quad (1)$$

Jensen's inequality can be used to show $D(P\|\mu) \geq 0$ and $D(P\|\mu) = 0$ if and only if $P \equiv \mu$. $D(P\|\mu)$ is thus an (asymmetric) index of the discrepancy between P and μ , and its definition is grounded in information theory and statistical mechanics. When $P = (P_1, \dots, P_H)$ and $\mu = (\mu_1, \dots, \mu_H)$ are probability measures on a discrete set with H elements, $D(P\|\mu) = \sum_{h=1}^H P_h \log\left(\frac{P_h}{\mu_h}\right)$. In the special case where $\mu_h \equiv 1/H$ is the uniform distribution, $D(P\|\mu)$ is the *Shannon entropy* $-\sum_h P_h \log P_h$.

Estimation by Entropy Minimization under Constraints

Let x denote a (vector) of random variable(s), β a (vector) of parameter(s), and $f(x, \beta)$ a (column vector) of real-valued function(s). Let $E_P[f(x, \beta)]$ denote its expectation computed with probability measure P . For a specific value of β , define the set of probability measures:

$$\mathcal{P}(\beta) \equiv \{P : E_P[f(x, \beta)] = 0\} \quad (2)$$

which additionally are absolutely continuous with respect to a distinguished measure μ that is determined by the application. Selection of a particular probability measure in $\mathcal{P}(\beta)$ is an example of *linear inverse problem*. One way to select a solution in stable manner is by picking the probability measure,

which minimizes the relative entropy with respect to μ under constraints

$$\begin{aligned} &\min_{P \in \mathcal{P}(\beta)} D(P\|\mu) \\ &\equiv \min_P \int \log(dP/d\mu) dP \quad \text{s.t. } E_P[f(x, \beta)] \\ &= 0 \end{aligned} \quad (3)$$

When μ is the uniform distribution on a finite set with H elements, $\mu_h \equiv 1/H$ and the constrained minimization of $D(P\|\mu)$ is equivalent to maximization of the *Shannon entropy* $-\sum_h P_h \log P_h$.

The solution to equation (3) is well known ([10], sec.3(A)) to have the following *Gibbs Canonical* or *Esscher Transformed* density (see **Esscher Transform**)

$$\frac{dP(\beta)}{d\mu} = \frac{e^{\gamma(\beta)' f(x, \beta)}}{E_{\mu}[e^{\gamma(\beta)' f(x, \beta)}]} \quad (4)$$

To compute the coefficient vector $\gamma(\beta)$ in equation (4), solve the following problem

$$\gamma(\beta) = \arg \max_{\gamma} I \equiv -\log E_{\mu}[e^{\gamma' f(x, \beta)}] \quad (5)$$

where the maximized value of I in equation (5) turns out to be the minimal relative entropy $D(P(\beta)\|\mu)$ in equation (3). This constrained minimum of relative entropy also has a frequentist interpretation from the large deviations (see **Large Deviations**) theory of IID processes, which will prove useful in motivating the parameter estimation procedure described later.

Application to Derivative Security Valuation

Consider the simplest problem of option pricing: value a European call option, written on a single underlying stock that pays no dividends, whose price at expiration T -periods ahead is denoted $x(T)$. The riskless, continuously compounded gross interest rate r is constant between now and expiration. Under the familiar assumptions of complete and frictionless markets that do not admit arbitrage opportunities, there is a *risk-neutral* probability measure P under which the call option's price C is the expected

value of its risklessly discounted payoff at expiration, that is,

$$C = E_P[\max[x(T) - K, 0]/r^T] \quad (6)$$

where the risk-neutral probabilities P satisfy the “martingale” constraint $x(0) = E_P\left[\frac{x(T)}{r^T}\right]$, rewritten as

$$E_P\left[\frac{x(T)}{x(0)r^T} - 1\right] = 0 \quad (7)$$

Risk-neutral pricing of options proceeds by specifying a parametric model for the risk-neutral stochastic price process of the underlying stock. Parameter values are found that make the model’s computed stock prices and/or option prices close (e.g., in the least-squares sense) to observed stock and/or option prices [4]. In the simplest case (the Black–Scholes model), this procedure requires an estimate of the volatility parameter, found either from past stock returns (i.e., historical volatility) or from market option prices (i.e., a best-fitting implied volatility).

However, suppose one has doubts about the correct parametric model. The formalism of the previous section provides an alternative. Let the scalar function $f(x, \beta) = \frac{x(T)}{x(0)r^T} - 1$, where $\beta = r$. The distribution μ is the forecast distribution of $x(T)$. To estimate this, one could just use a histogram of past T -period stock returns as in [27, 29], a conditional histogram [28], or a more complex forecasting model [13]. The distribution is then substituted into equation (5) and solved to find the $\gamma(\beta)$ needed to estimate the density $P(\beta)$ in equation (4), which is required to compute the option valuation (6). It is possible to extend the approach to handle stochastic dividends and interest rates.

Another approach presumes a particular form for μ , and defines a vector $f(x, \beta)$ with i th component $\max[x(T) - K_i, 0]/r^T - C_i$, where C_i is the observed market price for a call with exercise price K_i , as in [5, 19]. Then, equations (4)–(5) are used to study the nature of the measure $P(\beta)$ implied by those options’ market prices, while equation (6) could be used to value options *other* than those present in f . See [3, 7, 8] for some theoretical

and applied extensions of this approach. (*see also Weighted Monte Carlo*).

Further refinements were developed by Gray *et al.* [16], showing that the associated dynamic hedge (i.e., entropic hedge ratio) outperformed hedging benchmarks, and by Alcock and Carmichael [1], extending the concept to enable valuation of American options.

The entropic approaches are not necessarily inconsistent with the conventional approach. In fact, extant closed-form option pricing models can be analytically derived by specification of the process generating the stock price distributions, and systematically applying the **Esscher transform** (4) as in [12, 14].

Application to Parameter Estimation

A research program initiated by Hansen [17] first developed the generalized methods of moments (GMM) parameter estimator. Two entropy-based alternatives are defined, motivated by alternative frequentist estimation criteria suggested by large deviations theory (*see Cramér’s Theorem; Large Deviations*). We begin with this alternative frequentist criterion, and finish by describing its connection to entropy. Interpret β in equation (2) to be an unknown vector of parameters from a set Θ of possible parameter vectors, and $f(x; \beta) = (f_1, \dots, f_r)$ to be an r -component column vector of observable, real-valued functions. A time series of the random variable x is denoted $x_1, \dots, x_T$. The corresponding (random) sample average of the vector f is denoted $f_T(\beta) \equiv \sum_{i=1}^T f(x_i; \beta)/T$.

The empirical asset pricing literature considers processes for which a typical realization produces $\lim_{T \rightarrow \infty} f_T(\beta) = E[f(x; \beta)]$, where the expectations operator is, unless otherwise subscripted, taken with respect to the invariant measure μ of the process. So the probability of observing $f_T(\beta)$ in a compact neighborhood that does *not* contain the population mean $E[f(x; \beta)]$ must approach zero as $T \rightarrow \infty$. The *asymptotic rate* at which this probability goes to zero can be calculated by use of part of a powerful result of Ellis [11], expounded in [6], (pp. 20–22), and perhaps first used in asset pricing by Stutzer [26], (Appendix). Define the following extended, real-valued function of an r -component

vector γ :

$$\begin{aligned}\phi_T(\gamma; \beta) &\equiv \frac{1}{T} \log E \left[e^{\gamma' \sum_{t=1}^T f(x_t, \beta)} \right] \\ &= \frac{1}{T} \log E \left[\prod_{t=1}^T e^{\gamma' f(x_t, \beta)} \right] \quad (8)\end{aligned}$$

Define the asymptotic limit of equation (8) to be

$$\phi(\gamma; \beta) \equiv \lim_{T \rightarrow \infty} \phi_T(\gamma; \beta) \quad (9)$$

and the nonnegative, probability decay rate function

$$I(c) \equiv \sup_{\gamma} [\gamma' c - \phi(\gamma; \beta)] \quad (10)$$

$$\arg \min_{\beta} \left[I(0) = \sup_{\gamma} - \lim_{T \rightarrow \infty} \left(\phi_T(\gamma; \beta) \equiv \frac{1}{T} \log E \left[e^{\gamma' \sum_{t=1}^T f(x_t, \beta)} \right] \right) \right] \quad (13)$$

Then the probability of observing a value of the sample average lying within a closed (open) set C (O) that does *not* contain the population mean $E[f(x; \beta)]$, *decays* toward zero at a positive asymptotic *rate* that must be weakly larger (smaller) than $\inf_{c \in C} I(c; \beta)$ ($\inf_{c \in O} I(c; \beta)$).

Hansen [17] GMM framework estimates parameters and tests theoretical implications represented by the constraints:

$$\exists ! \beta^* : E[f(x; \beta^*)] = 0 \quad (11)$$

where β^* is the unique parameter vector (to be estimated) that satisfies the moment constraints.

Define $\mathcal{O}_\epsilon$ to be the open ϵ -ball about $E[f(x; \beta^*)] = 0$. Because the identification condition (11) implies that $E[f(x; \beta)] \neq 0$ when $\beta \neq \beta^*$, the probability of finding $f_T(\beta) \in \mathcal{O}_\epsilon$ decays to zero at an asymptotic rate weakly lower than $\inf_{c \in \mathcal{O}_\epsilon} I(c)$. Because the limit of this as $\epsilon \downarrow 0$ is $I(0)$, which is 0 if and only if $\beta = \beta^*$, a sensible estimation criterion is to search for a value of β making it as small as possible, that is, find $\arg \min_{\beta} I(0)$ [15]. Kitamura and Stutzer [23] show that when the vector f is Gaussian with stationary covariance sequence $E[(f(x_t; \beta) - E[f(x_t; \beta)])(f(x_{t-\tau}; \beta) - E[f(x_{t-\tau}; \beta)])'] \equiv \Gamma_\tau(\beta)$, $j = -\infty, \dots, +\infty$, this estimation criterion is

identical to the optimally weighted GMM criterion:

$$\begin{aligned}\arg \min_{\beta} I(0) &= \frac{1}{2} E[f(x; \beta)]' \\ &\times \left(\sum_{\tau=-\infty}^{+\infty} \Gamma_\tau(\beta) \right)^{-1} E[f(x; \beta)] \quad (12)\end{aligned}$$

forming the foundation for different feasible estimators, corresponding to different ways of estimating the population moments and infinite sum present in equation (12), though the large deviation interpretation (*see Large Deviations*) of equation (12) no longer holds outside of Gaussianity.^a

What can be done in more realistic cases where the researcher does not want to commit to specific distributional assumptions? The general criterion is

so a feasible estimator of equation (13) is needed. Fortunately, Kitamura [20] developed a smoothing approach to estimation, which was used in ([22], equation (9)) to produce an analog estimator [24] of the minimizing β in equation (13) (for proof, see [23]). Under regularity conditions listed there, they showed that this estimator is asymptotically equivalent to feasible, optimally weighted GMM in non-IID cases.

Entropic Interpretation

When the process is IID (but not necessarily Gaussian), $\phi_T(\gamma; \beta) = \log E[e^{\gamma' f(x; \beta)}]$, so $I(0) \equiv \max_{\gamma} -\log E[e^{\gamma' f(x; \beta)}]$ and the large deviations estimation (*see Large Deviations*) criterion (13) simplifies to the *exponential tilting* criterion, that is, $\arg \min_{\beta} [I(0) = \max_{\gamma} -\log E[e^{\gamma' f(x; \beta)}]]$. From equation (5) and the comment immediately following it, we see that the optimized value of the criterion may also be interpreted as the moment-constrained minimum of relative entropy in equation (3), in the IID special case.

In the general case (13), the aforementioned analog estimator developed in ([22], equation (9)) also has an entropic interpretation. It is the estimator that minimizes the relative entropy between the empirical

distribution of smoothed observations and the distribution of smoothed observations under the moment restriction.

Alternatively, when one substitutes $D(\mu \parallel P)$ for $D(P \parallel \mu)$ in equation (3) with no change in the rest of the formalism, the result is the *empirical likelihood* criterion [25]. From the view point of statistical inference and estimation, the empirical likelihood criterion $D(\mu \parallel P)$ achieves various optimality properties, especially in terms of large deviations [21]. First-order Taylor approximation of $D(\mu \parallel P)$ results in the χ^2 distance (see [9], p. 333), so substituting it for $D(\mu \parallel P)$ yields the *Euclidean Empirical Likelihood* criterion [2, 18]. Of course, the large deviations interpretation is different, due to the interchange of P and μ in the formalism.

End Notes

^aAlso, the choice of criterion function impacts the finite sample behavior of feasible estimators even under Gaussianity.

Risk Measures: Statistical Estimation

The recent interest in the estimation of risk measures is explained by changes in regulations in finance and insurance industries [4]. Ten years ago, the regulation was applied to a rather limited scope of assets and firms and only consisted in fixing minimal reserve level to hedge risky investments. However, these levels were computed without clear reference to the underlying risk. The new regulations, known as *Basel 2* for the finance industry and *Solvency 2* for the insurance industry, have proposed to account for risk in computing the reserves (Pillar 1). They also insist on the need for introduction of internal models by banks or insurance companies to follow their risk (Pillar 2) and on transparency (Pillar 3). This is a coherent program, which concerns risk modeling as well as the creation or the improvement of databases, and has to account for the heterogeneous technological level in these industries. In this article, we focus on risk measures, their computation, and updating.

In the current implementation of Basel 2 and Solvency 2, the risk measure suggested by regulators and generally retained by firms is the Value-at-Risk (VaR). This measure has several drawbacks, but has the advantage of being easily understood by practitioners. It can be presented as follows. Let us consider a given portfolio of assets. This portfolio can concern stocks, corporate bonds, consumer loans, or life insurance contracts. In practice, it corresponds to a business line of a bank, a credit institution, or an insurance company. The value of this portfolio at date t is denoted by W_t , but at this date its future values W_{t+h} are unknown.^a To hedge this uncertainty, some reserves R are introduced. With these reserves, the future portfolio value increases to $W_{t+h} + R$, which diminishes the potential loss. Let us fix a probability of loss $\alpha = 1, 5$, or 10% , say; then, the reserve level can be chosen such that

$$P_t[W_{t+h} + R < 0] = \alpha \quad (1)$$

where P_t denotes the probability given the information available at time t . By solving equation (1), we see that the reserve level is the opposite of the α -quantile of the distribution of the future portfolio value. It depends on the selected loss probability

α , investment horizon h , date t , information available at this date, and the set of selected assets. It can be denoted by $R(t, h; \alpha)$ and is written in a monetary unit as the dollar or the euro. For the determination of reserves, the admissible sets of assets, the level α , the horizon h , and the date of computations are imposed by the regulators. Other values can be selected by firms for internal use, especially for fixing and real-locating the so-called economic capital.

However, the portfolio value (W_t) generally features a nonstationary evolution, which can render difficulty in the determination of R . To circumvent this difficulty, it has been proposed to introduce the notion of VaR defined as

$$VaR(t, h; \alpha) = R(t, h; \alpha) + W_t \quad (2)$$

Thus, the VaR defined as

$$P_t[W_{t+h} - W_t < -VaR(t, h; \alpha)] = \alpha \quad (3)$$

is the opposite of the conditional α -quantile of the change in portfolio value ($W_{t+h} - W_t$), which is a much more stationary process.^b This definition highlights the importance of the (conditional) quantile function for building risk measures.

In the following section, we discuss properties that are suitable for risk measures. This allows to define a large class of risk measures, called *distortion risk measures (DRMs)*, which is flexible and includes the VaR as a special case. In the section Nonparametric Estimation in the IID Framework, we consider the estimation of DRMs, when the portfolio returns are independent of the past and identically distributed (IID). Under the IID assumption, the estimated risk measures have simple expressions in terms of returns, and it is easy to estimate their accuracy. These simple computations, which involve only a ranking of returns plus some averaging, explains the success of this practice, called *historical simulation*.

Nevertheless, the IID assumption is not realistic (see **Stylized Properties of Asset Returns**). For instance, it would be preferable to account for volatility persistence, for cycle effects, and so on. The introduction of serial dependences when computing and analyzing conditional risk measures is not an easy task and is only in its infancy for regulation purposes. Finally, we discuss the validation of the approaches used to compute the reserves and the coherent definitions of reserves for several business lines.

Risk Measures

First, we discuss the construction and the comparison of risk measures for a given date and a given horizon. For this reason, we do not indicate indexes t and h . Two axiomatic theories have been introduced in the literature to construct risk measures.

1. Coherent risk measures

The first constructive approach to evaluate the capital requirement was proposed by Artzner *et al.* [2]. $R(W)$ denotes the required reserve amount for a portfolio W , that is, for the future portfolio value W_{t+h} .

The axioms are as follows:

Distribution dependence: $R(W)$ depends only on the distribution of W .

Monotonicity: If W is more risky than W^* by the stochastic dominance^c of order 1, then $R(W) \geq R(W^*)$.

Drift invariance: $R(W + c) = R(W) - c$, for any W and any deterministic c .

Positive homogeneity: $R(\lambda W) = \lambda R(W)$, for any W and any nonnegative scalar λ .

Subadditivity: $R(W + W^*) \leq R(W) + R(W^*)$, for any W and W^* .

Note that the homogeneity and subadditivity properties imply the convexity of the coherent risk measure (see **Convex Risk Measures**).

2. The Wang axioms

The next set of axioms were introduced in a series of papers by Wang and Young [27], for the purpose of analyzing losses in insurance. Thus, we restrict ourselves to losses that are negative W . The axioms are as follows:

Distribution dependence: $R(W)$ depends on the distribution of W only.

Positivity: $R(W) \geq 0$.

Deterministic loss: $R(c) = -c$, for any deterministic loss $c < 0$.

Positive homogeneity: $R(\lambda W) = \lambda R(W)$ for any loss $W < 0$, and any nonnegative scalar λ .

Additivity for comonotonic risk: $R(W + W^*) = R(W) + R(W^*)$ for any losses W and W^* , which are increasing deterministic transformations of the same underlying risk Z .

Some of the above-mentioned conditions are easily written in terms of quantile functions, by noting that

- the quantile function of λW is λ times the quantile function of W and
- the quantile function of the sum $W + W^*$ of comonotonic risks is the sum of the quantile functions of W and W^* .

3. Distortion risk measures

A reserve level can be considered as a measure of risk. The interpretation in terms of quantile functions of the homogeneity and additivity for comonotonic risk assumptions implies that a risk measure satisfying Wang's set of axioms can be written as a linear functional of the quantile function. By applying the Riesz theorem, this leads to the introduction of the so-called distortion risk measures (DRM) defined by Wang [25, 26]:

$$\Pi(Q, H) = - \int_0^1 Q(u) dH(u) \quad (4)$$

where Q denotes the quantile function of the uncertain loss and H is a measure, called the *distortion measure*. The positivity axiom implies that H is a positive measure and the assumption of certain loss implies that H is a probability measure. Moreover, the DRM is coherent if H is concave. DRMs are the basis of the so-called “dual theory of choices under risk” [22, 27, 28]. Thus, a DRM is simply a weighted average of opposite quantile values. Well-known risk measures are derived by considering appropriate DRMs.

(a) VaR

When $H(u; \alpha) = \mathbf{1}_{(u \geq \alpha)}$, with $\alpha \in (0, 1)$, we get

$$\Pi(Q, H(\cdot; \alpha)) = -Q(\alpha) = VaR(\alpha) \quad (5)$$

(b) Tail-VaR

When $H(u, \alpha) = \min(u/\alpha, 1)$, with $\alpha \in [0, 1]$, we get the equally weighted average of VaR on the interval $[0, \alpha]$:

$$\begin{aligned} \Pi[Q, H(\cdot, \alpha)] &= - \int_0^\alpha \frac{Q(u)}{\alpha} du \\ &= - \frac{1}{\alpha} \int_0^\alpha u dF(u) \\ &= E[-W | W < -VaR(\alpha)] \end{aligned} \quad (6)$$

which is the opposite of the expected portfolio value when there is a loss; this measure is called the *Tail-VaR* at level α . This is a coherent risk measure since H is a concave function.

(c) Proportional hazard DRM

This risk measure is obtained for the power law transformation $H(u; p) = u^p$, where $p \geq 0$ and has been introduced for the definition of insurance premium.

Nonparametric Estimation in the IID Framework

In this section, we assume a sequence of IID returns concerning a given portfolio, and consider the estimation of the risk measures by their sample counterpart. Since these measures are defined from the quantile function, we first recall the asymptotic behavior of the empirical quantile. Then, we deduce the properties of estimated distortion risk measures.

The Empirical Quantile Function

$y_1, \dots, y_T$ denotes the sequence of IID returns, with a common distribution with pdf f , cdf F , and quantile function Q . The empirical cdf is defined as

$$\hat{F}_T(y) = \frac{1}{T} \sum_{i=1}^T \mathbf{1}_{y_i \leq y} \quad (7)$$

whereas the empirical quantile function is

$$\hat{Q}_T(u) = \inf\{y : \hat{F}_T(y) \geq u\} \quad (8)$$

When the distribution is continuous with positive pdf, the empirical cdf and quantile functions are asymptotically related by means of the Bahadur representation [19, Section 4.3]:

$$\begin{aligned} \sqrt{T}[\hat{Q}_T(u) - Q(u)] \\ = -\frac{1}{f[Q(u)]} \sqrt{T}[\hat{F}_T[Q(u)] - u] + o_P(1) \end{aligned} \quad (9)$$

where $o_P(1)$ is negligible in probability. This asymptotic equivalence allows for deriving the asymptotic behavior of the empirical quantile from the asymptotic behavior of the empirical cdf.

It is well known that the empirical cdf is strongly consistent with the true underlying cdf and converges weakly, that is, in distribution, to a Brownian bridge up to an appropriate standardization [23]:

$$\sqrt{T}[\hat{F}_T(Q(u)) - u] \Rightarrow B(u), u \in [0, 1] \quad (10)$$

where $\Rightarrow$ denotes weak convergence and B is a Brownian bridge, that is, a Gaussian process with zero mean and covariance: $\text{Cov}[B(u_1), B(u_2)] = \min(u_1, u_2) - u_1 u_2$. By applying the Bahadur representation (9), we deduce that

$$\sqrt{T}[\hat{Q}_T(u) - Q(u)] \Rightarrow -\frac{1}{f[Q(u)]} B(u) \quad (11)$$

Empirical Distortion Risk Measures

Let us now consider a given risk measure:

$$\Pi(Q, H) = \int_0^1 Q(u) dH(u) \quad (12)$$

where H is the distortion measure. Its empirical counterpart is given by

$$\hat{\Pi}_T(H) = \Pi(\hat{Q}_T, H) = -\int_0^1 \hat{Q}_T(u) dH(u) \quad (13)$$

It is easily written in terms of observed returns. Let us consider the returns ranked in increasing order as $y_1^* \leq y_2^* < \dots < y_T^*$, called the *order statistic*. We have

$$\hat{\Pi}_T(H) = -\sum_{i=1}^T \{y_i^* [H(i/T) - H((i-1)/T)]\} \quad (14)$$

This estimator is a linear combination of the order statistics $y_1^* < \dots < y_T^*$, with weights depending on the sample size.^d

Formula (14) is especially simple for estimating a VaR, that is, the opposite of the value of the α -quantile, when the sample size is well chosen. Indeed, let us assume, for instance, a risk level $\alpha = 5\%$ and $T = 200$; the estimated VaR (5%) is simply

$$\widehat{VaR}_T(5\%) = -y_{10}^* \quad (15)$$

(since $5\% \times 200 = 10$).

Asymptotic Behavior of Estimated DRM

The asymptotic behavior of the estimated DRM is directly deduced from the asymptotic behavior of the empirical quantile function. The estimator $\hat{\Pi}_T(H)$

converges to the theoretical DRM, $\Pi(Q; H)$, and we have

$$\begin{aligned} & \sqrt{T}[\hat{\Pi}_T(H) - \Pi(Q, H)] \\ & \Rightarrow \int_0^1 \frac{1}{f[Q(u)]} B(u) dH(u) \end{aligned} \quad (16)$$

This means that the estimated DRM is asymptotically Gaussian, with zero mean and a variance given by

$$\begin{aligned} & V_{as}\{\sqrt{T}(\hat{\Pi}_T(H) - \Pi(Q, H))\} \\ & = \int_0^1 \int_0^1 \frac{\min(u_1, u_2) - u_1 u_2}{f[Q(u_1)]f[Q(u_2)]} dH(u_1) dH(u_2) \end{aligned} \quad (17)$$

This expression of the asymptotic variance can be difficult to use in practice, since it involves the pdf, which is rather difficult to estimate. It can

$$\begin{aligned} & V_{as}\{\sqrt{T}[T\widehat{VaR}(\alpha) - TVaR(\alpha)]\} \\ & = \frac{V[Y|Y \leq -VaR(\alpha)] + (1 - \alpha)[TVaR(\alpha) - VaR(\alpha)]^2}{\alpha} \end{aligned} \quad (21)$$

be simplified when the DRM is continuous with distortion density h . Indeed, we get

$$\begin{aligned} & V_{as}\{\sqrt{T}[\hat{\Pi}_T(H) - \Pi(Q, H)]\} \\ & = \int_0^1 \int_0^1 \frac{[\min(u_1, u_2) - u_1 u_2]}{f[Q(u_1)]f[Q(u_2)]} \\ & \quad \times h(u_1)h(u_2) du_1 du_2 \\ & = \int_0^1 \int_0^1 [\min(u_1, u_2) - u_1 u_2] \\ & \quad \times h(u_1)h(u_2) dQ(u_1) dQ(u_2) \end{aligned} \quad (18)$$

by noting that $1/f[Q(u)]$ is the quantile density. Therefore, we get

$$\begin{aligned} & V_{as}\{\sqrt{T}[\hat{\Pi}_T(H) - \Pi(Q, H)]\} \\ & = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} [\min(F(y_1), F(y_2)) - F(y_1)F(y_2)] \\ & \quad \times h[F(y_1)]h[F(y_2)] dy_1 dy_2. \end{aligned} \quad (19)$$

Example 1 (Sample VaR). The $VaR(\alpha)$ is obtained with the distortion measure equal to the point mass at α . The distortion measure is not continuous and formula (19) cannot be applied. From the general result, we know that

$$\begin{aligned} & \sqrt{T}[\widehat{VaR}_T(\alpha) - VaR(\alpha)] = -\sqrt{T}[\hat{Q}_T(\alpha) \\ & - Q(\alpha)] \rightsquigarrow N\left[0, \frac{1}{f[Q(\alpha)]}\alpha(1 - \alpha)\right] \end{aligned} \quad (20)$$

The accuracy of this estimator depends not only on the risk level α but also on the tail behavior of the distribution, since the density f (generally) tends to zero at infinity. Thus, the estimator of the VaR is not very accurate for small probability of loss α , and the lack of accuracy increases with increase in magnitude of the tail.

Example 2 (Sample Tail-VaR). By applying formula (19), the asymptotic variance of the estimated Tail-VaR [15] is

where TVaR denotes the Tail-VaR.

This asymptotic variance has two components. The first one measures the variability of the loss when a loss occurs, and the second one accounts for the expected loss beyond the VaR.

Estimated Accuracy of a Sample DRM

It is important to distinguish the case of continuous distortion measures, which exclude the VaR.

1. Continuous distortion measure

When H is continuous with density h , we can directly use the sample counterpart of formula (19) to derive a consistent estimator of the variance of $\hat{\Pi}_T(H)$ [15, 18]. We get

$$\begin{aligned} & \hat{V}_{as}(\sqrt{T}[\hat{\Pi}_T(H) - \Pi(Q; H)]) \\ & = \sum_{i=1}^{T-1} \sum_{j=1}^{T-1} \left\{ \left(\min\left(\frac{i}{T}, \frac{j}{T}\right) - \frac{i}{T} \frac{j}{T} \right) \right\} \end{aligned}$$

$$\times h\left(\frac{i}{T}\right)h\left(\frac{j}{T}\right)(y_{i+1}^* - y_i^*)(y_{j+1}^* - y_j^*)\} \quad (22)$$

2. Discrete distortion measure

Formula (19) cannot be applied to the VaR. Since

$$V_{\text{as}}\left(\sqrt{T}[\hat{Q}_T(\alpha) - Q(\alpha)]\right) = \frac{1}{f[Q(\alpha)]}\alpha(1-\alpha) \quad (23)$$

this variance can be estimated by

$$\hat{V}_{\text{as}}\left(\sqrt{T}[\hat{Q}_T(\alpha) - Q(\alpha)]\right) = \frac{1}{\hat{f}_T(\hat{Q}_T(\alpha))}\alpha(1-\alpha) \quad (24)$$

where $\hat{f}_T$ is, for instance, a kernel estimator of the density.

Dynamic Analysis

Despite its success among practitioners, the computation and analysis of VaR and DRM in an IID framework is not realistic, and the (nonlinear) return dynamics should be taken into account. It arises in the computation of the risk measure itself, which depends on the conditional quantile function.^c In this conditional framework, a nonparametric approach is difficult to follow, since the number of conditioning variables can be rather large, including current and lagged values of several asset returns, for instance. This explains why parametric or semiparametric approaches are generally considered, with the risk of using a misspecified model, that is, of introducing an additional model risk. In the first subsection, we consider a conditionally Gaussian model and derive the corresponding estimators of the DRM. The second subsection concerns the term structure of VaR. In the third subsection, we discuss dynamic models recently introduced for the purpose of computing dynamic VaR. These models are directly written in terms of conditional quantile functions.

Parametric Dynamic Models

1. Definition of the dynamic DRM

The dynamic model is generally written for the portfolio returns of interest $y_1, \dots, y_T$. Let us assume that

the conditional distribution of y_t , given observable variables z_{t-1} , say, is such that

$$y_t = m(z_{t-1}; \theta) + \sigma(z_{t-1}; \theta)u_t \quad (25)$$

where (u_t) are the IID standard Gaussian variables and θ is an unknown parameter. $m(z_{t-1}; \theta)$ (respectively, $\sigma(z_{t-1}; \theta)$) is the conditional drift (respectively, conditional volatility). The conditional quantile function is

$$Q_t(u) = m(z_{t-1}; \theta) + \sigma(z_{t-1}; \theta)\Phi^{-1}(u) \quad (26)$$

where Φ denotes the cdf of the standard normal. We deduce that a dynamic DRM can be written as

$$\begin{aligned} \Pi(Q_t, H) &= - \int_0^1 Q_t(u) dH(u) = -m(z_{t-1}; \theta) \\ &\quad - \sigma(z_{t-1}; \theta) \int_0^1 \Phi^{-1}(u) dH(u) \end{aligned} \quad (27)$$

The DRM depends on the information by means of the conditional mean and volatility and is a linear combination of these summary statistics.

This type of analysis is usually applied with autoregressive conditionally heteroscedastic (ARCH) models or switching regime models [6], and is easily extended to error terms with no Gaussian distribution, such as the Student distribution.

For instance, such an approach is followed by J.P. Morgan with an IGARCH model defined by

$$y_t = \sigma_t u_t \quad (28)$$

where

$$\sigma_t^2 = \theta \sigma_{t-1}^2 + (1-\theta)y_{t-1}^2 = (1-\theta) \sum_{j=1}^{\infty} \theta^{j-1} y_{t-j}^2 \quad (29)$$

and $\theta = 0.95$. Such an automatic dynamic, assumed valid for any portfolio return, is likely misspecified, and it is preferable to estimate the return dynamics separately for each portfolio.

2. Estimation of the dynamic DRM

The DRM is usually estimated in two steps. In the first step, the parameter θ is estimated by (conditional) maximum likelihood (ML), that is, by maximizing

$$\hat{\theta}_T = \arg \max_{\theta} \sum_{t=1}^T \left\{ -\frac{1}{2} \log \sigma^2(z_{t-1}; \theta) - \frac{1}{2} \frac{[y_t - m(z_{t-1}; \theta)]^2}{\sigma^2(z_{t-1}; \theta)} \right\} \quad (30)$$

This estimator has the standard asymptotic properties of an ML estimator. Then, in the second step, the DRM is estimated as

$$\hat{\Pi}_{t,T} = -m(z_{t-1}; \hat{\theta}_T) - \sigma(z_{t-1}; \hat{\theta}_T) \int_0^1 \Phi^{-1}(u) dH(u) \quad (31)$$

For instance, we have

$$\widehat{VaR}_T(t; \alpha) = -m(z_{t-1}; \hat{\theta}_T) - \sigma(z_{t-1}; \hat{\theta}_T) \Phi^{-1}(\alpha) \quad (32)$$

The first step is valid for any type of DRM and can be applied to get a coherent set of estimated risk measures, such as $VaR(1\%)$, $VaR(5\%)$, $VaR(10\%)$, and $TVaR(10\%)$.

The Term Structure of VaR

Until now, we focused on the evolution of the dynamic risk measure, that is, on its dependence with respect to time for a fixed horizon $h = 1$. It is interesting to consider how the risk measure depends on the horizon h for a fixed date t . If y_{t+1} denotes the opposite change of portfolio value between t and $t + 1$, the opposite change of portfolio value between t and $t + h$ is $y_{t,h} = y_{t+1} + \dots + y_{t+h}$. Therefore, the conditional quantile function of interest $Q_{t,h}$ is now associated with the conditional distribution of $y_{t,h}$ given the information at time t .

The term structure of VaR is the mapping

$$h \rightarrow VaR(t, h; \alpha) = -Q_{t,h}(\alpha) \quad (33)$$

which can be defined for any date t and probability level α .

In simple cases, the term structure of VaR is derived explicitly. For instance, let us assume a Gaussian autoregressive process of order 1 for the short-term opposite portfolio change

$$y_t = \mu + \varphi(y_{t-1} - \mu) + \sigma u_t \quad (34)$$

where μ, φ, σ are the mean, autoregressive coefficient, and innovation variance, respectively, and (u_t) is a sequence of IID standard Gaussian variables. Thus, the conditional distribution of $y_{t,h}$ is Gaussian, with mean

$$m(y_t, h) = \mu h + \varphi \frac{1 - \varphi^h}{1 - \varphi} (y_t - \mu) \quad (35)$$

and variance

$$\sigma^2(h) = \frac{\sigma^2}{(1 - \varphi^2)} \left\{ h - 2\varphi(1 - \varphi^h) + \varphi^2 \frac{1 - \varphi^{2h}}{1 - \varphi^2} \right\} \quad (36)$$

We deduce the VaR at horizon h as

$$VaR(t, h; \alpha) = -m(y_t, h) - \sigma(h) \Phi^{-1}(\alpha) \quad (37)$$

The IID Gaussian framework is obtained when $\varphi = 0$. In this case, we have $VaR(t, h; \alpha) = -\mu h - \sigma \sqrt{h} \Phi^{-1}(\alpha)$, and the term structure involves both a linear and square-root function of the horizon h . This formula is often used by practitioners with $\mu = 0$ to derive automatically the VaR at horizon h from the VaR at horizon 1 by $VaR(t, h; \alpha) = \sqrt{h} VaR(t, 1; \alpha)$. As seen earlier, this simplified formula is valid under very restrictive assumptions and has to be systematically avoided.

In fact, it is necessary to carefully compute the VaR at the different horizons case by case. In general, the term structure of VaR has no explicit expression, but can be derived by simulation, whenever the short-term quantile function $Q_{t,1}$ has an explicit expression: $Q_{t,1}(u) = Q(u; y_{t-1})$, say, if we assume for illustration, a Markov process. The simulation procedure is as follows:

1. Consider independent drawings $u_{t+1}^s, \dots, u_{t+h}^s$ in the standard uniform distribution on $(0, 1)$

2. Apply the recursive formula

$$\begin{aligned} y_{t+1}^s &= Q(u_{t+1}^s, y_t) \\ y_{t+2}^s &= Q(u_{t+2}^s, y_{t+1}^s) \\ y_{t+h}^s &= Q(u_{t+h}^s, y_{t+h-1}^s) \end{aligned} \quad (38)$$

$(y_{t+1}^s, \dots, y_{t+h}^s)$ has the same conditional distribution as $(y_{t+1}, \dots, y_{t+h})$.

3. Replicate $s = 1, \dots, S$, and approximate $Q_{t,h}(\alpha)$ by the empirical quantile distribution of $y_{t,h}^s = y_{t+1}^s + \dots + y_{t+h}^s$, $s = 1, \dots, S$.

Dynamic Quantile Models

Specification. Since the dynamic DRM is easily written in terms of the conditional quantile function, it has been recently proposed to directly specify the dynamic model for (y_t) in terms of function Q_t , instead of using more standard (nonlinear) autoregressive specifications [11, 13]. For instance, a dynamic additive quantile (DAQ) model is

$$Q_t(u; \theta) = \sum_{k=1}^K a_k(\underline{y}_{t-1}; \alpha_k) Q_k(u; \beta_k) + a_0(\underline{y}_{t-1}; \alpha_0) \quad (39)$$

where $\underline{y}_{t-1} = (y_{t-1}, y_{t-2}, \dots)$, Q_k are path-independent baseline quantile functions with identical range $(-\infty, +\infty)$ and $a_k(\underline{y}_{t-1}; \alpha_k)$, $k = 1, \dots, K$ are non-negative functions of the past. $\theta = (\alpha'_0, \dots, \alpha'_K, \beta'_1, \dots, \beta'_K)'$ is the vector of parameters. The positivity restrictions on functions a_k ensure that $Q_t(\cdot; \theta)$ is an increasing function and thus is compatible with the quantile interpretation.

The DAQ model encompasses simple specifications of interest. For instance, specifications of the type

$$\begin{aligned} Q_t(u) &= Q_0(u) + Q_1(u) \max(y_{t-1}, 0) \\ &\quad + Q_2(u) \max(-y_{t-1}, 0) \end{aligned} \quad (40)$$

or

$$\begin{aligned} Q_t(u) &= \gamma_0(u) + \gamma_1(u) Q_{t-1}(u) + \gamma_2(u) |y_{t-1}| \\ &= \frac{\gamma_0(u)}{1 - \gamma_1(u)} + \sum_{k=1}^{\infty} \gamma_2(u) \gamma_1(u)^k |y_{t-k}| \end{aligned} \quad (41)$$

are special cases of the conditional autoregressive variance at risk (CAViaR) models introduced by Engle and Manganelli [9]. A specification such as

$$\begin{aligned} Q_t(u) &= m_0 + m_1 |y_{t-1} - \mu| \\ &\quad + (\sigma_{0,0} + \sigma_{0,1} |y_{t-1} - \mu|)^{1/2} \Phi^{-1}(u) \\ &\quad + (\sigma_{1,0} + \sigma_{1,1} |y_{t-1} - \mu|)^{1/2} tg[\pi(u - 1/2)] \end{aligned} \quad (42)$$

defines a quantile mixture of a Gaussian distribution (with baseline quantile function Φ^{-1}) and a Cauchy distribution (with baseline quantile function $tg[\pi(u - 1/2)]$), with ARCH effects in both scale parameters and a risk premium in the location parameter.

For a DAQ model, the dynamic DRM are immediately derived as

$$\begin{aligned} \Pi(Q_t, H) &= \sum_{k=1}^K a_k(\underline{y}_{t-1}; \alpha_k) \int Q_k(u; \beta_k) dH(u) \\ &\quad + a_0(\underline{y}_{t-1}; \alpha_0) \end{aligned} \quad (43)$$

They depend on the same set of dynamic summaries of the past $a_k(\underline{y}_{t-1}; \alpha_k)$, $k = 0, \dots, K$, with sensitivity coefficients equal to the baseline DRMs. These explicit expressions (see examples (40)–(42)) are appropriate for easily deriving the term structure of VaR by simulation (see the section The Term Structure of VaR).

Estimation. When the dynamic model is directly written in terms of a quantile function with a simple expression of Q_t , it can be numerically cumbersome to derive the conditional pdf $f_t(y) = \left(\frac{dQ_t}{du} [Q_t^{-1}(y)] \right)^{-1}$, which requires the inversion of function Q_t at each observation date. As a consequence, it can be difficult to derive the maximum likelihood estimate of the parameter θ .

Different estimation approaches have been proposed in the statistical literature.

1. When $Q_t(u; \theta) = Q(u; \theta)$ is independent of the path, the parameter θ can be estimated by calibrating on L -moments or trimmed L -moments [8, 17]. The theoretical L -moments or trimmed L -moments are of the type $\int Q(u; \theta) P_l(u) du$, $l = 1, \dots, L$, where P_l are well-chosen

polynomials and their sample counterparts are $\frac{1}{T} \sum_{i=1}^T y_i^* P_i(t/T)$, where $y_1^* < \dots < y_T^*$ is the order statistic, that is, the observations $y_1, \dots, y_T$ are ranked in increasing order. This approach is easy to implement, but does not provide efficient estimators, and is difficult to extend to a dynamic framework [see the Generalized Method of L -Moments in [13, Section 4].

2. In the dynamic framework, the parameter θ can also be consistently estimated by minimizing an objective function of the type in [20]:

$$\begin{aligned} \hat{\theta}_T &= \arg \min_{\theta} \sum_{t=1}^T \{ \alpha \max[y_t - Q_t(\theta), 0] \\ &\quad + (1 - \alpha) \max[Q_t(\theta) - y_t, 0] \} \\ &= \arg \min_{\theta} \sum_{t=1}^T \{ \alpha [y_t - Q_t(\theta)]^+ \\ &\quad + (1 - \alpha) [y_t - Q_t(\theta)]^- \} \end{aligned} \quad (44)$$

where α is a scalar between 0 and 1 (see the section The Control Problem for the interpretation of the objective function).

3. The estimation methods above are easy to apply, but are generally not efficient. They can be used as starting values in the optimization algorithm of the estimated inverse Kullback–Leibler information criterion (KLIC) :

$$\begin{aligned} \hat{\theta}_T &= \arg \max_{\theta} \sum_{i=1}^T \left\{ \int_0^1 \log \left[\frac{dQ}{du}(u|y_{t-1}; \theta) \right] \right. \\ &\quad \left. + \int_0^1 \log \hat{f}_T[Q(u|y_{t-1}; \theta)|y_{t-1}] \right\} du \end{aligned} \quad (45)$$

where $\hat{f}_T$ is a kernel estimator of the conditional pdf of y_t given y_{t-1} . The inverse KLIC estimator is asymptotically equivalent to the ML estimator and asymptotically efficient [13].

Control and Out-of-sample Validation

The current regulations have at least three limitations: (i) the large use of the VaR to measure the risk and fix the required capital. This measure

accounts for the probability of loss, but not for the magnitude of the loss beyond the VaR. This drawback can be corrected by considering another DRM such as the Tail-VaR. (ii) The lack of coherency between the suggested (but often not followed) computation of the VaR as a conditional quantile, and the *ex post* validation of this computation by the regulator, which is generally based on a historical (that is unconditional) analysis. (iii) The computation of VaR is performed independently for each business line without taking into account the potential dependence between the risks of different lines.

The two latter limitations can be solved by considering the problem of the determination of reserves as a control problem [12, 16].

The Control Problem

The concept of VaR has been initially defined in a rather *ad hoc* way, but is the solution of an optimal control problem. More precisely, let us consider the objective function

$$\psi(t, z_t) = E_t[\alpha(y_{t+1} + z_t)^+ + (1 - \alpha)(y_{t+1} + z_t)^-] \quad (46)$$

where α is the announced risk level. The decision criterion corresponds to an asymmetric loss function, which distinguishes two types of errors. When $y + z < 0$, the reserve level is not large enough to hedge the loss; when $y + z > 0$, the reserve level is too high. The type I error has to be avoided from the prudential point of view of the regulator, whereas the type II error has to be avoided for the firm, since the reserves receive no the interest rate in the current regulation.

The solution of the optimization problem (46) [19],

$$\begin{aligned} \hat{z}_t &= \arg \max_{z_t} E_t[\alpha(y_{t+1} + z_t)^+ \\ &\quad + (1 - \alpha)(y_{t+1} + z_t)^-] \end{aligned} \quad (47)$$

performed over the variables z_t function of the information, is

$$\hat{z}_t = -Q_t(\alpha) = VaR_t(\alpha) \quad (48)$$

Thus, the reserve level can be interpreted as a control variate and the conditional VaR as the optimal control variate.

In this control framework, the optimal value of the criterion function is given as [24]

$$\begin{aligned}\psi(t, \hat{z}_t) &= \alpha P_t[y_{t+1} > -\hat{z}_t] \\ &\times E_t[(y_{t+1} + \hat{z}_t)^+ | y_{t+1} > -\hat{z}_t] + (1 - \alpha) \\ &\times P_t[y_{t+1} < \hat{z}_t] E_t[(y_{t+1} + \hat{z}_t)^- | y_{t+1} < -\hat{z}_t] \\ &= \alpha(1 - \alpha)[TVaR^+(\alpha) + TVaR^-(\alpha)]\end{aligned}\quad (49)$$

where $TVaR^+$ and $TVaR^-$ are the Tail-VaR associated with the right and left tails of the conditional distribution, respectively. Thus, if the VaR is used as the reserve level, the Tail-VaRs have also to be computed and provide the optimal value of the decision criterion.

Specification Test

In practice, it is usual to check the validity of the proposed reserve levels $\widehat{VaR}_t$ by comparing the announced level α with the frequency of exceedance dates with $y_t + \widehat{VaR}_t < 0$. This practice is misleading. Indeed, two different procedures for determining the reserves can give the same frequency, 5%, say, but the dates at which the reserves are not sufficient can be equally located with the first procedure and come in cluster with the second one. Clearly, if $T = 100$, the second procedure, in which losses will cumulate over five periods, say, is more risky. An appropriate validation has to distinguish these situations.

In fact, the first-order conditions of the control problem are as follows:

$$\frac{\partial \psi}{\partial z}(t, \hat{z}_t) = 0 \Leftrightarrow E_t[\mathbf{1}_{y_{t+1} + \hat{z}_t < 0}] = \alpha \quad (50)$$

which is the definition of the conditional VaR, that is,

$$P_t[y_{t+1} + \hat{z}_t < 0] = \alpha \quad (51)$$

The first-order condition (50) is a conditional moment restriction. As usual, it can be replaced by a set of unconditional moment restrictions by introducing instrumental variables g_t , which are observable functions of the past. We get

$$E[g_t(\mathbf{1}_{y_{t+1} + \hat{z}_t < 0} - \alpha)] = 0 \quad \forall g_t \quad (52)$$

Specification tests can be constructed from the sample counterparts of these restrictions; the test

compares the statistics $(1/T) \sum_{t=1}^T g_t(\mathbf{1}_{y_{t+1} + \hat{z}_t < 0} - \alpha)$ to zero, after an appropriate standardization.

The current practice, considering the historical frequency $(1/T) \sum_{t=1}^T (\mathbf{1}_{y_{t+1} + \hat{z}_t < 0} - \alpha)$, thus, selects $g_t = 1$ as the single instrumental variable. Clearly, other instrumental variables have also to be considered to detect the persistence in extreme losses, such as

$$g_{1,t} = \mathbf{1}_{y_t + \hat{z}_{t-1} < 0}, g_{2,t} = \mathbf{1}_{y_{t-1} + \hat{z}_{t-2} < 0}, \dots \quad (53)$$

which indicate the lack of reserve in the past.

Dependent Business Lines

Let us consider two business lines, say, $y_{1,t}$, $y_{2,t}$. The current regulation suggests to compute separately the VaR for the two lines, with the same α , that is, to compute $VaR_{1,t}(\alpha)$, $VaR_{2,t}(\alpha)$. Then, the total reserve is $VaR_{1,t}(\alpha) + VaR_{2,t}(\alpha)$. This regulation does not account for the dependence between the two risks. The question of reserve allocations between business lines is difficult. A possible solution introduced by Gourioux and Liu [16] focuses on the definition of an appropriate decision criterion. By analogy with the control problem described in the section The Control Problem, we may consider the objective function:

$$\begin{aligned}\psi(t; z_{1t}, z_{2t}) &= E_t\{[\alpha(y_{1,t+1} + z_{1t})^+ + (1 - \alpha)(y_{1,t+1} + z_{1t})^-] \\ &\times [\alpha(y_{2,t+1} + z_{2t})^+ + (1 - \alpha)(y_{2,t+1} + z_{2t})^-]\}\end{aligned}\quad (54)$$

which distinguished four types of errors, which are type I and II errors cross with business lines. If the loss variables $y_{1,t+1}$ and $y_{2,t+1}$ are conditionally independent, the objective function is equal to the product:

$$\begin{aligned}E_t[\alpha(y_{1,t+1} + z_{1t})^+ (1 - \alpha)(y_{1,t+1} + z_{1t})^-] \\ \times E_t[\alpha(y_{2,t+1} + z_{2t})^+ + (1 - \alpha)(y_{2,t+1} + z_{2t})^-]\end{aligned}\quad (55)$$

and the solutions of the control problem are simply the VaR computed per business line.

$$\hat{z}_{1,t} = VaR_{1,t}(\alpha), \hat{z}_{2,t} = VaR_{2,t}(\alpha) \quad (56)$$

If the loss variables are dependent, the optimization of the objective function (54) provides another

solution, which accounts for the dependence between extreme risks. The advantage of this approach, based on the direct optimization of the control decision criterion, is that it is easy to extend to any number of business lines and can provide a solution without having to estimate or specify the joint distribution of $(y_{1,t+1}, y_{2,t+1})$.

Concluding Remarks

The new regulations have led to a rethink on the whole question of risk measures in term of reserve levels and to see the determination of reserves as a control problem. As a consequence, the standard volatility risk measure is progressively being replaced by the VaR, Tail-VaR, or another DRM for several financial problems such as portfolio management [1, 5, 10, 14, 21], performance comparisons [7], or even derivative pricing, especially in insurance [3, 25].

End Notes

^aThus, we implicitly assume that the current portfolio value is known. This assumption is satisfied for assets that are highly traded on the markets, but should be discussed for over-the-counter (OTC) products.

^bThe portfolio returns $(W_{t+h} - W_t)/W_t$ can be even more stationary; the corresponding α -quantile becomes $-VaR(t, h; \alpha)/W_t$.

^cEquivalently if the cumulative distribution function (cdf) of W is smaller than the cdf of W^* .

^dThis is called an *L-statistic* in the statistical literature.

^eIt also arises when computing the VaR by historical simulation, since the asymptotic properties of the sample quantile, especially the asymptotic variance–covariance matrix, are modified under serial dependence.

Mixture of Distribution Hypothesis

The mixed distribution hypothesis (MDH) in finance maintains heavy tails in price fluctuations $\Delta X(t)$ that can be explained by embedding randomized time $\xi(t)$. Intuitively, the net price change $\Delta X(t)$ over period t is hypothesized to be the sum of $\xi(t)$ incremental interperiod steps, say $\Delta X_{t,i}$, giving

$$\Delta X(\xi(t)) = \sum_{i=1}^{\xi(t)} \Delta X_{t,i} \quad (1)$$

Randomized time $\xi(t)$ can be thought of as the amount of economic time or the number of information events that traders actually experience during t , typically associated with volume-traded $V(t)$. The resulting convolution $\Delta X(\xi(t))$ has a mixed distribution that can capture leptokurtosis, explain heterogeneity, including conditional heteroscedasticity, and improve model fitting similar to nonparametrics. Applications abound in finance (equity returns, bond prices) and macroeconomics (income, unemployment, exchange rates).

The statistical foundations of mixtures are well known [7]. If $y(t) := \Delta X(t)$ has density $f_y(y; \xi)$ and economic time $\xi(t) \geq 0$ has density $f_\xi(\xi)$, then the observed convolution $y(\xi(t))$ has a density mixture

$$f_{y(\xi)}(y) = \int_0^\infty f_y(y; \xi) f_\xi(\xi) d\xi \quad (2)$$

See [22] for a survey of mixture models, including generalized gamma and beta, log-Cauchy and lognormal.

The use of compound or mixed distributions to explain leptokurtosis in price fluctuations $\Delta X(t)$, while retaining a finite variance, first appears in the finance literature in the 1960s^a. A sequence of papers, including [25, 26], and prominently Clark [4], exploited in various ways a subordinated finite variance process model $\Delta X(\xi(t))$ as a direct response to Mandelbrot's [20] controversial α -stable hypothesis of aggregate prices. The latter "extreme value theory" framework permits infinite variance, but at a cost of estimation and inference challenges (*see* [5, 17]). Nevertheless, only the α -stable laws form a

closed distribution class under affine transformations: finite variance α -stable laws are the Gaussian laws that are necessarily symmetric, and infinite variance α -stable laws permit asymmetry, making this class attractive for applied statistical analysis in finance (*see* [28] for an encyclopedic treatment of the α -stable laws).

Tests of MDH against nonmixtures, including normality or α -stability, have mixed results [12, 21, 30], and there exists a sharp identification problem that is typically ignored (*consider* [19]). The subordinated process premise has successfully evolved into randomized volatility [1, 3, 11], which now receives vigorous attention in the finance literature [8, 9, 11, 27] and extreme value theory literature [14, 15, 18]; some applications of distribution mixtures in finance are motivated by specification flexibility rather than explaining heavy tails [10].

In the remainder of this article, we discuss at length Clark's [4] seminal model, noting the early attempts to improve on it, and conclude with remarks on recent extensions in the stochastic volatility literature.

Randomized Time and Subordination

Clark's [4] influential model of asset returns exploits Bochner's [2] and Feller's [7] work on subordinated Gaussian processes. Denote by μ_y , σ_y^2 , and κ_y respectively the mean, variance, and kurtosis of y , and $\sigma_{y|z}^2(t)$ is the conditional variance, given random z .

If $\{X(t)\} \equiv \{X(t) : -\infty < t < \infty\}$ is a stochastic process and $\{\xi(t)\}$, $\xi : \mathbb{N} \rightarrow \mathbb{R}_+$, is a "driving process" then the stochastically indexed $X(\xi(t))$ is "subordinated" to $X(t)$. If $\{\Delta\xi(t)\}$ is stationary and independent with mean $\mu_{\Delta\xi} > 0$, and^b $\Delta X(t) \stackrel{\text{iid}}{\sim} (0, \sigma_{\Delta X}^2)$, then the subordinated fluctuations $\Delta X(\xi(t))$ are stationary and independent, and distributed:

$$\Delta X(\xi(t)) \stackrel{\text{iid}}{\sim} (0, \mu_{\Delta\xi} \times \sigma_{\Delta X}^2) \quad (3)$$

Since $\mu_{\Delta\xi}$ reflects the arrival of new information, in Clark's model only the average amount of new information effects the dispersion of embedded returns $\sigma_{\Delta X(\xi)}^2$. If, in addition, price fluctuations are normally distributed $\Delta X(t) \stackrel{\text{iid}}{\sim} N(0, \sigma_{\Delta X}^2)$ and $\sigma_{\Delta\xi}^2 < \infty$ and $\Delta\xi(t)$ are independent of $X(t)$, then price

fluctuations $\Delta X(\xi(t))$ have kurtosis

$$\kappa_{\Delta X(\xi)} = 3 \left(1 + \frac{\sigma_{\Delta \xi}^2}{\mu_{\Delta \xi}^2} \right) > 3 \quad (4)$$

a simple positive function of $\sigma_{\Delta \xi}^2$, and larger than 3, the benchmark value for normals and therefore for what is considered canonically to be heavy tailed. The tails of price fluctuations $\Delta X(\xi(t))$ grow heavier as the variance $\sigma_{\Delta \xi}^2$ of information flow increases, and are heavy tailed in the strict sense of being thicker than normals for any directing process $\{\xi(t)\}$ with $\sigma_{\Delta \xi}^2 > 0$. Further, as in [4], if iid $\Delta \xi(t)$ are lognormal with parameters $\{c, v^2\}$ then

$$\begin{aligned} \mu_{\Delta \xi} &= \exp\{c + v^2/2\} \text{ and } \sigma_{\Delta \xi}^2 \\ &= \exp\{2c + v^2\} \times [\exp\{v^2\} + 1] \end{aligned} \quad (5)$$

and from equation (1) the convolution $y(\xi(t)) \equiv \Delta X(\xi(t))$ is lognormal-normally distributed as follows:

$$\begin{aligned} f_y(y) &= \frac{1}{2\pi\sigma_{\Delta X}^2\sigma_{\Delta \xi}^2} \int_0^\infty u^{-3/2} \\ &\times \exp \left\{ \frac{-(\ln u - c)^2}{2v^2} - \frac{y^2}{2u\sigma_{\Delta X}^2} \right\} du \end{aligned} \quad (6)$$

Volume-traded $V(t)$ may be positively associated with economic time $\xi(t)$, in which case equity returns should be heavier tailed during periods of substantial trader activity. Heimstra and Jones [13], for example, use this prediction to test for variance causality from volume to returns under a finite variance assumption.

Many models for relating randomized time to volume have been suggested. See [16] for a survey. Clark [4] used the parametric specification

$$\sigma_{\Delta X|\xi}^2(t) = \beta V(t)^\gamma, \text{ where } \beta, \gamma > 0 \quad (7)$$

for the log-price $X(t)$ of cotton future prices. Epps and Epps [6] use a parsimonious parametric asset price model to support Clark's mixtures of distribution model. Tauchen and Pitts [29] propose an asset price model that relates price fluctuations to volume via a variance-components framework with trader-specific and traderwide shocks. Unlike Clark their model predicts $\Delta X(t)$ and $V(t)$ are independent

for each transaction, but have moments with common parameters. For example, $\sigma_{\Delta X}^2$ and μ_V are both increasing functions of the variance of the trader-specific shock and therefore exhibit spurious positive association (as opposed to Clark's *ad hoc* association).

Stochastic volatility models for asset returns inherently exploit the premise that a mixture of distributions captures the arrival of news, making this literature the latest offshoots of Clark's model [1, 11, 27]. The Brownian semimartingale framework for stochastic volatility has become dominant in the option pricing literature by permitting volatility clustering and accounting for market incompleteness (which abnegates option redundancy), providing flexible extensions of the Black–Scholes option pricing model. See, especially, **Stochastic Volatility Models** and **Econometrics of Option Pricing** in this volume, and consult [9, 23].

End Notes

^aEvidently Newcomb [24] first used a mixture of normal distributions to account for numerous “discordant” observations (i.e., heavy tails), with an application to planetary orbits.

^b $y \sim (\mu, \sigma^2)$ implies y is distributed with mean μ and variance σ^2 . iid stands for “independent and identically distributed”.

Market Microstructure Effects

Most asset pricing models assume that markets are in equilibrium, but not how asset prices move from one equilibrium to another. Market microstructure is the area of economics that studies how prices adjust to new information and how the trading mechanism affects this adjustment process. In a perfect market, new information would be immediately disseminated and interpreted by all market participants. In this full information setting, prices would immediately adjust to a new equilibrium value determined by the agents' preferences and the content of the information. This immediate adjustment, however, is not likely to hold in practice. Not all relevant information is known by all market participants at the same time. Furthermore, information that becomes available is not processed at the same speed by all market participants, implying variable lag time between a news announcement and the agents' realization of price implications. Much of modern microstructure theory is, therefore, driven by models of asymmetric information and the learning process of the market.

In this asymmetric information setting, there are two general areas of interest. First, we can study the process by which the market prices converge to prices that accurately reflect new information. This is termed the *price discovery process*. Learning occurs through time and therefore empirical analysis of this process examines time series properties of asset prices.

The second area of interest studies market quality. In an ideal market, all trades would occur costlessly at a single price where that price accurately reflects all relevant information. In reality, prices for buyers and sellers differ. This difference is determined by the cost of making market (day-to-day operations costs), the risk faced by a market maker that the price will move against their current inventory position, and the risk of trading against better informed agents. All these risks imply that a market maker must be compensated for his/her risk. Higher quality markets will exhibit smaller cost. O'Hara [5] provides a thorough introduction to the economics of market microstructure.

Both these areas, price discovery and market quality, require the study of the fine grain, detailed

price data. In an asymmetric information setting, agents learn about the value of the asset from order flow. A trader with information that says the asset is undervalued will tend to buy the asset and *vice versa*. In this spirit, price impact studies measure how prices adjust to characteristics of order flow. Market quality measures assess the difference between available prices (such as quotes) or trade prices and a notional fair market price. Much of empirical market microstructure uses high-frequency, intraday and often trade-by-trade data.

Here, we focus on econometric issues and models for high-frequency data. We begin with a discussion of the types of data available. Properties of the data are discussed and relevant models are presented.

Data

High-frequency data generally refer to data that are collected at a very rapid rate. The most fundamental data are prices and quantities; however, there might be more than one type of price and more than one type of quantity that can be reported. Many data sets report transaction prices that are the price paid for in a given trade and the quantity (the number of shares) transacted. These are usually referred to as *transaction prices* and *trade size*. The second type of price and quantity data is the limit order book. The limit order book refers to a set of prices and quantities available for sale (on the ask side of the market) and buy (on the bid side of the market). New information arrival might correspond to a change in any of these prices or quantities. These data sets can be quite large. A frequently traded asset such as IBM might have more than 30 000 trades in a single day and significantly many more updates to the limit order book.

In most markets, trades or updates to the limit order book do not occur at regularly spaced intervals, but rather at the pace of the market. Most data sets contain one observation each time that a new piece of information arrives and a time stamp indicating a recorded time at which the transaction or change took place.

The most popular data source for high-frequency US equities is the trades and quotes (TAQ) data set available through Wharton Research Data Services. High-frequency foreign exchange data are becoming more readily available now. One source that has

been around for a while is Olsen and Associates. Other markets such as options and futures markets are slowly becoming available as well. High-frequency data sets are now more readily available for fixed income, such as GovPX, which offers tick-by-tick US treasury prices and volume.

Features of High-frequency Data

Figure 1 presents 2 h of trade-by-trade price data for the stock Airgas (ticker symbol ARG). The horizontal axis is the local time of day. Price data are probably the most fundamental data and there are several things that become immediately apparent. First, the data are not regularly spaced in time. From 10:30 to 11:00 there are about eight trades that occur, but from 11:00 to 11:30 there are many more. Trades occur when individuals make trade decisions, not on a regular schedule.

The second feature that is apparent is that the prices fall on a grid. The smallest increment in the grid is referred to as the *tick size*. US stocks have recently undergone a transition from trading in one-eighth of a dollar to decimalization. This transition was initially tested for 7 NYSE stocks in August 2000 and was completed for the NYSE listed stocks on January 29, 2001. NASDAQ began testing with 14 stocks on March 12, 2001 and completed the transition on April 9, 2001. In June 1997, NYSE permitted 1/16th prices.

When high-frequency data are viewed across multiple days, many relevant variables exhibit diurnal,

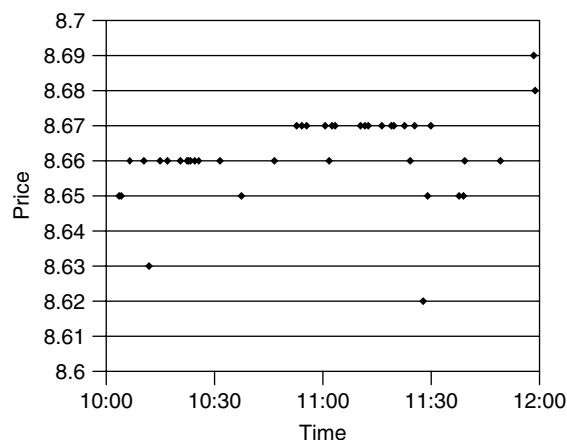

Figure 1 Trade-by-trade transaction prices for airgas

or within day patterns. For example, the volatility of asset price returns over fixed intervals tends to exhibit a U shape in most markets. Volatility is highest in just after the open and just before the close. Other examples of a similar pattern driven by the open and close of the market can be found in bid–ask spreads, trading activity, and traded volume.

Unlike their lower frequency counterparts, market microstructure effects sometimes induce strong correlations in observed, high-frequency returns. Trade-to-trade returns often exhibit negative correlation as the price “bounces” back and forth between trades at the ask price and trades at the bid price.

Some Useful Modeling Approaches

High-frequency data have interesting features to challenge the empirical investigator. In this section, we provide a brief introduction to different modeling approaches that have proven useful. Engle and Russell [3] provide a more detailed discussion of high-frequency data and modeling approaches.

Fixed Interval Models

Most econometric techniques are designed for models with equally spaced data. There is a natural inclination to aggregate irregularly spaced data into the familiar fixed interval setting and apply standard techniques. Returns can be computed over fixed intervals such as 5 min. Since prices are not continuous, there will, in general, not be a price posted exactly at the end of each interval. Hence, a choice will have to be made as to how to define the prices. The prevailing price method uses the last available price before, or at, the end of the interval. Another choice is to interpolate a value for the price given the two prices immediately surrounding the end of the interval. For very frequently traded assets (relative to the interval size), there will generally be a price near the end of the interval, but for short intervals or infrequently traded assets this is not guaranteed. The lack of well-defined prices becomes particularly important when multivariate models are considered. Prices may be stale (old) if the prevailing price method is used so that prices do not reflect recent information if a trade has not occurred in some time, or prices will reflect future information if interpolation is used. Either case can result in erroneous relationships.

Once the prices are aggregated to the fixed interval, then standard techniques can be applied. This temporal aggregation has proven particularly attractive in modeling volatility. Once the spacing of the data is regular, standard volatility models such as GARCH models (*see GARCH Models*) can be applied. Dynamics of the mean can be studied using traditional ARMA or vector autoregression (VAR) time series approaches.

Event Time Models

This class of models indexes the observation in event time. If the data are trade-by-trade data, then these models index time by the trade number. The first observation is the first trade, the second observation is the second trade, and so on. This approach neglects the temporal (clock time) spacing of the data and treats the data series as if the clock that determines the updating to the process is a “trade clock”. If traders update their beliefs about prices each time a trade is made, then there is no role for clock time and this approach appears reasonable. Again, standard time series techniques can be applied to the series such as GARCH models (*see GARCH Models*) or ARMA models (*see Autoregressive Moving Average (ARMA) Processes*).

This approach is not well suited for simultaneously modeling more than one return series, as each will be operating on their own trade time. For this reason, multivariate analysis of return series for more than one asset generally relies on fixed interval approaches. A notable exception is multivariate models for characteristics of a trade (like volume or whether the trade is a buyer or seller initiated) and returns for the same stock. Since both series are updated at the same random time intervals, they both operate on the same time scale. A seminal paper by Hasbrouck [4] uses VAR models for TAQ to study the price impact of a trade on future prices.

Tick time models are also unlikely to be suitable for volatility modeling. Clearly, the longer the time interval between price observations, the larger the volatility should be. While a component of volatility is related to the transaction process and therefore is updated in trade time, another component of volatility is due to the passage of time and potential (nontrade) information.

Point Process Models

A different approach views the data as a point process (*see Point Processes*). A point process is simply a sequence of random arrival times $t_1, t_2, t_3, \dots$, where $t_i \geq t_{i-1}$. These arrival times might correspond to trade times so that t_1 is the time (clock time) that the first trade occurred, t_2 is the time of the second trade, and so on. There may be information associated with each arrival time such as the price or the volume associated with the trade. If r_i denotes the return from the $i - 1$ th trade to the i th trade, then the sequence of arrival times and prices (t_i, r_i) forms a marked point process. Many questions of economic interest can be formulated in the context of the joint conditional distribution $f(t_i, r_i | F_{i-1})$, where F_{i-1} is information available at the time of the $i - 1$ th trade. This distribution completely describes the probability of when and what will happen to the price.

Clearly, the sequence event arrival times can be described by t_i or by the durations between events $x_i = t_i - t_{i-1}$. It may be difficult to directly specify this joint conditional distribution, so Engle [1] proposed decomposing the distribution into $f(x_i, r_i | F_{i-1}) = g(r_i | x_i, F_{i-1})h(x_i | F_{i-1})$, where g is the distribution of the price given the time the event happened (and the history F_{i-1}) and h is the marginal distribution of when the event occurs. Engle and Russell [2] proposed the autoregressive conditional duration (ACD) model for the distribution of the arrival times $h(x_i | F_{i-1})$ (*see Duration Models*). Models for the mark (the price in this case) can then be fit using standard techniques conditional on the duration. The model operates in event time, but as the distribution is conditional on the time since the last trade, calendar time effects can be captured.

Engle [1] proposed a GARCH model for $g(r_i | x_i, F_{i-1})$ where the volatility explicitly depends on the time passed since the last trade. Russell and Engle [6] proposed a model for discrete returns $g(r_i | x_i, F_{i-1})$ that explicitly accounts the time passed since the last trade. Both models suggest that the passage of calendar time is important in models of returns.

The three modeling strategies outlined here (fixed interval, event time, and point processes) comprise the bulk of the approaches but there are others. We do not discuss unobserved component models where the price is modeled as a latent process with bid and ask prices determined by noisy perturbations of a true

price. We also did not touch on an important and growing literature that links market microstructure effects to asset prices. That is, if investors have preferences for assets that can be easily traded, then the ease of trade of the asset may affect the equilibrium price. Finally, we do not discuss optimal execution strategies or models of transaction cost.

Simulation-based Estimation

Simulation-based estimation methods were first used in microeconomic models involving qualitative or limited dependent endogenous variables and, possibly, lagged endogenous variables (see, in particular, [13, 14]) and in macroeconomic models [11, 12]. In this literature, the role of simulations was to approximate likelihood functions or moments which are not computable exactly, and the origin of the computational problem was often the occurrence of large-size integrals when passing from characteristics of the latent model to those of the observable model.

In financial econometrics, the computational problem comes from the simultaneous presence of dynamics and latent variables. Such a situation may imply, for instance, a likelihood function defined as a multivariate integral the size of which is astronomical. Let us look more precisely at the genesis of the problem.

Many financial econometric models can be written in the form

$$\begin{cases} y_t = r_{1t}(\underline{y}_{t-1}, \underline{y}_t^*, \varepsilon_{1t}; \theta) \\ y_t^* = r_{2t}(\underline{y}_{t-1}, \underline{y}_{t-1}^*, \varepsilon_{2t}; \theta) \end{cases} t = 1, \dots, T \quad (1)$$

where y_t is an observable endogenous vector, y_t^* is an unobservable endogenous vector, θ is an unknown vector, ε_{1t} and ε_{2t} are independent unobservable error white noises (the distributions of which can be assumed to be known without loss of generality), $\underline{y}_t$ is a notation for $(y_t, y_{t-1}, \dots)$.

From system (1) it is, in general, easy to derive the conditional probability density function (pdf):

$$f(y_t / \underline{y}_{t-1}, \underline{y}_t^*; \theta) \\ \text{and} \quad f(y_t^* / \underline{y}_{t-1}, \underline{y}_{t-1}^*; \theta)$$

and, therefore, the joint pdf:

$$f(\underline{y}_T, \underline{y}_T^*; \theta) = \prod_{t=1}^T f(y_t / \underline{y}_{t-1}, \underline{y}_t^*, \theta) f(y_t^* / \underline{y}_{t-1}, \underline{y}_{t-1}^*, \theta) \quad (2)$$

However since $\underline{y}_T^*$ is unobserved the likelihood function is

$$l_T(\underline{y}_T; \theta) = \int f(\underline{y}_T, \underline{y}_T^*; \theta) d\underline{y}_T^* \quad (3)$$

Even if y_T^* is scalar, we are facing an integral of size T , to which the standard numerical methods cannot be applied. For instance, in the simplest case where each y_t^* can take only two values the previous integral is a sum of 2^T terms. If $T = 100$, which is very small in finance, we have 2^{100} terms. So standard numerical procedures are of no use. Note, however, that recursive algorithms are available in some special cases (the Kalman filter in the linear case and the Kitagawa–Hamilton in the case where y_t^* takes a finite number of values and appears in the model with a fixed number of lags).

Examples of Models of Type Governed by Equations (1)

1. Stochastic volatility models

$$y_t = \exp(y_t^*) \varepsilon_{1t} \quad (4)$$

$$y_t^* = \theta_1 + \theta_2 y_{t-1}^* + \varepsilon_{2t} \quad (5)$$

$$\varepsilon_{1t} \sim N(0, 1), \varepsilon_{2t} \sim N(0, \theta_3) \quad (6)$$

2. Factor ARCH model

$$y_t = \theta_1 y_t^* + \varepsilon_{1t}, \quad y_t : \text{multivariate} \\ (\theta_{11} = 1) \quad (7)$$

$$y_t^* = (\theta_2 + \theta_3 y_{t-1}^{*2})^{1/2} \varepsilon_{2t} \quad (8)$$

$$\varepsilon_{1t} \sim N(0, \Sigma(\theta_4)) \quad (9)$$

$$\varepsilon_{2t} \sim N(0, 1) \quad (10)$$

where y_t is a vector and y_t^* a univariate latent ARCH driving the whole dynamics.

3. Diffusion process observed at discrete dates

If we observe the diffusion,

$$d\tilde{y}_t = a(\tilde{y}_t, \theta) + \sigma(\tilde{y}_t, \theta) dW_t \quad (11)$$

(where W_t is a standard Brownian motion) at $t = 1, \dots, T$, we can consider the Euler approximation corresponding to time unit $\frac{1}{n}$ (n is an integer chosen by the econometrician to have a good

approximation):

$$\tilde{y}_\tau = \tilde{y}_{\tau-\frac{1}{n}} + \frac{1}{n}a(\tilde{y}_{\tau-\frac{1}{n}}, \theta) + \frac{1}{\sqrt{n}}\sigma(\tilde{y}_{\tau-\frac{1}{n}}, \theta)\varepsilon_\tau \quad (12)$$

where τ takes the values $\frac{k}{n}$, $k = 1, 2, \dots$ and the sequence ε_τ is a standard Gaussian white noise. The $\tilde{y}_\tau$ are observed only if τ is an integer. Renaming $\tilde{y}_\tau = y_k^*$, $\varepsilon_\tau = \varepsilon_{1k}$, we have

$$y_k^* = y_{k-1}^* + \frac{1}{n}a(y_{k-1}^*, \theta) + \frac{1}{\sqrt{n}} \times \sigma(y_{k-1}^*, \theta)\varepsilon_{1k} \quad (13)$$

$$y_k = y_k^*, \text{ if } k \text{ multiple of } n \\ = 0, \text{ otherwise (by convention)} \quad (14)$$

which is of type (1) (k replacing t).

Simulation Methods

The econometric methods described below are based on different simulation methods, which can be partitioned into three categories.

The first category is made of *unconditional simulations* obtained in the following way. Drawing a sequence $(\tilde{\varepsilon}_{1t}^s, \tilde{\varepsilon}_{2t}^s, t = 1, \dots, T)$ in the known distribution of $(\varepsilon_{1t}, \varepsilon_{2t})$, choosing initial values for y_t and y_t^* , and using equation (1), we can, for any value of θ , compute simulated paths $\{y_t^s(\theta), y_t^{*s}(\theta), t = 1, \dots, T\}$. These simulations are unconditional in the sense that they do not depend on the observed values $y_1, \dots, y_T$.

The second category is made of *sequentially conditional simulations*. Using formulas (2) and (3) we see that if, for a given value of θ , we draw sequentially $y_t^{*s} = 1, \dots, T$ in $f(y_t^*/y_{t-1}, y_{t-1}^*; \theta)$, where y_{t-1} are the observed values, we get an *unbiased simulator* of the likelihood function $f(y_T; \theta)$, namely, $\Pi_{t=1}^T f(y_t/y_{t-1}, y_t^{*s}, \theta)$, since

$$l(y_T; \theta) = E \Pi_{t=1}^T f(y_t/y_{t-1}, y_t^{*s}, \theta) \quad (15)$$

the expectation being taken with respect to the probability with pdf

$\Pi_{t=1}^T f(y_t^{*s}/y_{t-1}, y_{t-1}^{*s}; \theta)$. Therefore, $f(y_T; \theta)$ is the limit when S goes to infinity of

$$\frac{1}{S} \sum_{s=1}^S f(y_t^{*s}/y_{t-1}, y_{t-1}^{*s}; \theta) \quad (16)$$

However, in practice, this convergence is often very slow and must be improved by importance sampling methods [1, 4].

In the third category, we have the *globally conditional simulations*. The aim is to simulate in the global conditional distribution with pdf $f(y_T^*/y_T, \theta)$, for a given θ . Note that the previous sequential drawing does not provide such a global drawing; a sequential procedure giving such a drawing should be based on the sequence of pdfs $f(y_t^*/y_T, y_{t-1}^*; \theta)$ (y_T replacing y_{t-1}), but this is not feasible since $f(y_t^*/y_T, y_{t-1}^*; \theta)$ is not computable. More generally, the problem seems to have no solution since

$$f(y_T^*/y_T; \theta) = \frac{f(y_T, y_T^*; \theta)}{f(y_T; \theta)} \quad (17)$$

and the denominator is not computable. The key remark to solve the problem is that this denominator is constant, for given (y_T, θ) , and therefore we can use simulation techniques that only require us to know the pdf up to a multiplicative constant. The more important techniques satisfying these conditions are Monte Carlo Markov chain (MCMC) techniques like the Hastings–Metropolis algorithm.

In a first method, the likelihood function, which is not easily computable, is replaced by another objective function, the optimization of which gives consistent asymptotically normal estimators. Examples of such a method are the indirect inference (II) method [9], briefly described below, and the method of simulated moments [5], which is a particular case of the II method.

The second kind of methods is based on an approximation of the maximum likelihood estimator. For instance, the simulated likelihood ratio method [2] is based on the identity

$$\frac{l(y_T, \theta)}{l(y_T; \bar{\theta})} = E_{\bar{\theta}} \left[\frac{l(y_T, y_T^*; \theta)}{l(y_T, y_T^*; \bar{\theta})} / y_T \right] \quad (18)$$

for any given $\bar{\theta}$. Therefore a globally conditional simulation $\underline{y}_T^{*s}$ in $f(\underline{y}_T^*/\underline{y}_T; \theta)$ provides the unbiased simulator $\frac{l(\underline{y}_T, \underline{y}_T^{*s}; \theta)}{l(\underline{y}_T, \underline{y}_T^{*s}; \bar{\theta})}$ of $\frac{l(\underline{y}_T; \theta)}{l(\underline{y}_T; \bar{\theta})}$ and the ratio can be consistently approximated by an empirical mean of such unbiased simulations. Another example is the simulated expectation maximization (EM) method [15]. The EM algorithm is based on the maximization in θ at iteration m of $E_{\theta^{(m)}}[\log f(\underline{y}_T, \underline{y}_T^*, \theta)/\underline{y}_T]$; this conditional expectation is, in general, not computable but, again, can be approximated using globally conditional simulations.

The third approach is the Bayesian approach. Given a prior distribution of θ , with pdf $\pi(\theta)$, the Bayesian approach is based on the posterior pdf $\pi(\theta/\underline{y}_T)$. Since

$$\pi(\theta/\underline{y}_T) = \frac{f(\theta, \underline{y}_T)}{f(\underline{y}_T)} = \frac{f(\underline{y}_T; \theta)\pi(\theta)}{f(\underline{y}_T)} \quad (19)$$

the computation of $\pi(\theta/\underline{y}_T)$ seems impossible and, moreover, a simulation in this pdf seems also impossible since it is not even known up to a multiplicative constant.

The key idea here is to consider the joint posterior pdf of θ and $\underline{y}_T^*$ given $\underline{y}_T$, which is

$$f(\theta, \underline{y}_T^*/\underline{y}_T) = \frac{f(\underline{y}_T, \underline{y}_T^*; \theta)\pi(\theta)}{f(\underline{y}_T)} \quad (20)$$

The numerator of equation (20) is now computable and therefore, simulations in this joint distribution can be made, giving approximations of not only $\pi(\theta/\underline{y}_T)$ but also of the *smoothing* distribution $f(\underline{y}_T^*/\underline{y}_T)$. See [3].

Indirect Inference

Let us consider an auxiliary criterion $Q_T(\underline{y}_T, \beta)$, where β is an auxiliary parameter. We assume that, when T goes to infinity, $Q_T(\underline{y}_T, \beta)$ converges to a deterministic function $Q_\infty(\theta_0, \beta)$, and we denote by $b(\theta)$ the function obtained by $b(\theta) = \arg \max_\beta Q_\infty(\theta, \beta)$. The function $b(\cdot)$ is called a *binding function* and is assumed to be injective. The II estimators are obtained in the following way:

- First step Compute

$$\hat{\beta}_T = \arg \max_\beta Q_T(\underline{y}_T, \beta) \quad (21)$$

- Second step Compute

$$\hat{\theta}_{ST}(\Omega) = \arg \min_\theta [\hat{\beta}_T - \hat{\beta}_{ST}(\theta)]' \Omega [\hat{\beta}_T - \hat{\beta}_{ST}(\theta)] \quad (22)$$

where

$$\hat{\beta}_{ST} = \arg \max_\beta \sum_{s=1}^S Q_T[\underline{y}_T^s(\theta), \beta] \quad (23)$$

$\underline{y}_T^s(\theta)$ being an unconditional simulated path corresponding the value θ of the parameter of interest and Ω a symmetric positive definite matrix.

Two asymptotic equivalent versions of $\hat{\theta}_{ST}(\Omega)$ are obtained if in equation (21) $\hat{\beta}_{ST}(\theta)$ is replaced either by

$$\frac{1}{S} \sum_{s=1}^S \beta_T^s(\theta) \quad (24)$$

with $\beta_T^s(\theta) = \arg \max_\beta Q_T[\underline{y}_T^s(\theta), \beta]$ or by

$$\tilde{\beta}_{ST}(\theta) = \arg \max_\beta Q_{ST}[\underline{y}_{ST}^s(\theta), \beta] \quad (25)$$

Note, however, that the latter equivalence requires that

$$\frac{\partial Q_T}{\partial \beta}(\underline{y}_T, \beta) = \sum_{t=1}^T \frac{\partial Q_1(y_t; \beta)}{\partial \beta} \quad (26)$$

Finally we also obtain a class of estimators $\hat{\theta}_{ST}(\Sigma)$, which is globally asymptotically equivalent to the class $\hat{\theta}_{ST}(\Omega)$ [6] by

$$\hat{\theta}_{ST}(\Sigma) = \arg \min_\theta \left(\sum_{s=1}^S \frac{\partial Q_T[\underline{y}_T^s(\theta), \hat{\beta}_T]}{\partial \beta'} \right) \Sigma \left(\sum_{s=1}^S \frac{\partial Q_T[\underline{y}_T^s(\theta), \hat{\beta}_T]}{\partial \beta} \right) \quad (27)$$

A clear advantage of these methods is that the basic model has only been used through the path simulations $y_T^s(\theta)$. Therefore the only requirement made on the model is the possibility of performing these path simulations, which is generally satisfied.

When S is fixed and T goes to infinity the II estimators are consistent and asymptotically normal. The asymptotic variance–covariance matrix depends on Ω and this matrix can be optimally chosen. Note, however, that, if θ and β have the same size, Ω does not matter asymptotically. Specification tests can be based on the optimal values of equation (21) for the optimal matrix Ω , and the classical asymptotic significance tests (score test, Wald test, or a test based on the optimal values of the criteria providing the estimators) are also available.

The general ideas of the II can also be used in other domains: corrections for second-order bias [10], notions of indirect information and indirect identification [8, 9], and encompassing [7].

An important issue of the II methodology is the choice of Q_T and natural candidates are log-likelihood functions of approximations of the model retained or approximations of the log-likelihood function of this model.

Econometrics of Diffusion Models

Many models in finance take the form of stochastic differential equations, where the variable of interest X_t is a vector of asset prices, interest rates, and so on, with dynamics of the form

$$dX_t = \mu(X_t; \theta)dt + \sigma(X_t; \theta)dW_t \quad (1)$$

where W_t is an m -dimensional standard Brownian motion. In a typical parametric situation, the functions μ and σ are known, but not the parameter vector θ , which is to be estimated. In the base case, the data are discrete observations on the process X_t sampled at dates $\Delta, 2\Delta, \dots, n\Delta$, on a time interval $[0, T]$ with $T = n\Delta$ and Δ fixed. The case where Δ is either deterministic and time varying or random (as long as independent from X) introduces no further fundamental difficulties. This article focuses exclusively on the case where Δ need not be small, that is, exclude the vast array of methods specifically designed only for high-frequency data.

A number of methods are available to estimate θ . First maximum-likelihood estimation is discussed, followed by nonlikelihood alternatives.

Maximum-likelihood Estimation

Well-established principles from statistics indicate that in this context maximum-likelihood estimation of θ is the method of choice. One should write down as a function of θ the probability of collecting the observations we have actually obtained, and pick the value of θ that maximizes this function, known as the *likelihood function*. In other words, the resulting estimator of θ is the one that makes it most likely that the model would have produced the data we obtained.

Furthermore, the form of the likelihood function is particularly simple due to the Markovian nature of the model (1). The probability of observing the data $\{X_0, X_\Delta, \dots, X_{n\Delta}\}$, given that the parameter vector is θ , is

$$\begin{aligned} & \mathbb{P}(X_{n\Delta}, X_{(n-1)\Delta}, \dots, X_0; \theta) \\ &= \mathbb{P}(X_{n\Delta} | X_{(n-1)\Delta}, \dots, X_0; \theta) \end{aligned}$$

$$\begin{aligned} & \times \mathbb{P}(X_{(n-1)\Delta}, \dots, X_0; \theta) \\ &= \mathbb{P}(X_{n\Delta} | X_{(n-1)\Delta}; \theta) \\ & \times \mathbb{P}(X_{(n-1)\Delta}, \dots, X_0; \theta) \\ &= \mathbb{P}(X_{n\Delta} | X_{(n-1)\Delta}; \theta) \times \dots \\ & \times \mathbb{P}(X_\Delta | X_0; \theta) \mathbb{P}(X_0; \theta) \end{aligned} \quad (2)$$

where the first equality is simply Bayes' rule and the second is a consequence of Markov property. Repeating the process for each successive observation yields the third equality. The objective is then to maximize over values of θ , this function or equivalently its log

$$\ell_N(\theta) \equiv \sum_{i=1}^n l_X(X_{i\Delta} | X_{(i-1)\Delta}, \Delta; \theta) \quad (3)$$

where $l_X(x | x_0, \Delta; \theta) = \ln p_X(x | x_0, \Delta; \theta)$ and $p_X(x | x_0, \Delta; \theta)$ is the transition density of the process, or the probability that X will go from x_0 to x in the amount of time Δ , when the parameter vector is θ .

All this is indeed exceedingly simple, except for one not so minor detail: with few exceptions, we do not know in closed form the expression of the transition density p_X corresponding to a given model (1)! In finance, the exceptions are the well-known models of Black and Scholes [10] (the geometric Brownian motion $dX_t = \beta X_t dt + \sigma X_t dW_t$), Vasicek [37] (the Ornstein–Uhlenbeck process $dX_t = \beta(\alpha - X_t)dt + \sigma dW_t$) and Cox *et al.* [18] (Feller's square-root process $dX_t = \beta(\alpha - X_t)dt + \sigma X_t^{1/2} dW_t$) which rely on these existing closed-form expressions. The fact that these models have closed-form derivative prices is, of course, not by coincidence, since a derivative price is the expected value of its payoff under the density p_X corresponding to the risk-neutral version of the model. So knowledge of the density in closed form and closed-form option prices is closely related.

In many cases that are relevant in finance, however, the transition function is unknown: see, for example, the models used in [16] ($dX_t = \beta(\alpha - X_t)dt + \sigma X_t dW_t$), [31] ($dX_t = (\alpha X_t^{-(1-\delta)} + \beta)dt + \sigma X_t^{\delta/2} dW_t$), [17]; the more general version of Chan *et al.* [11] ($dX_t = \beta(\alpha - X_t)dt + \sigma X_t^\gamma dW_t$), [14] ($dX_t = (\alpha_0 + \alpha_1 X_t + \alpha_2 X_t^2)dt + (\sigma_0 + \sigma_1 X_t) dW_t$); the affine class of models in [20] and [19] ($dX_t = \beta(\alpha - X_t)dt + \sqrt{\sigma_0 + \sigma_1 X_t} dW_t$); and the nonlinear mean reversion model in [1] ($dX_t = (\alpha_0 + \alpha_1 X_t + \alpha_2 X_t^2 + \alpha_{-1}/X_t)dt + (\beta_0 + \beta_1 X_t + \beta_2 X_t^{\beta_3})dW_t$).

A method to construct accurate approximations in closed form to the unknown transition density $p_X(x|x_0, \Delta; \theta)$ for an arbitrary diffusion model (1) is described later.

Constructing the Likelihood Function

The construction of the function l_X to be used in equation (3) follows [2] (examples and application to interest rate data), [3] (univariate theory), and [4] (multivariate theory). The method proceeds by constructing a closed-form expansion to approximate the transition density p_X , or equivalently l_X directly. While the description below may seem involved, in practice these calculations can be implemented in software such as *Mathematica*. Alternative methods would involve solving numerically a partial differential equation, or employing simulations, neither one delivering a closed-form approximation to l_X . The closed-form method has been shown to be substantially more accurate and faster in practical implementations than the alternatives [28, 29].

Reducibility

Whenever possible, it is advisable to start with a change of variable. A diffusion X is *reducible* if and only if there exists a one-to-one transformation of the diffusion X into a diffusion Y whose diffusion matrix σ_Y is the identity matrix. That is, there exists an invertible function $\gamma(x; \theta)$ such that $Y_t \equiv \gamma(X_t; \theta)$ satisfies the stochastic differential equation:

$$dY_t = \mu_Y(Y_t; \theta)dt + dW_t \quad (4)$$

Every univariate diffusion is reducible, through the simple transformation $Y_t = \int^{X_t} du/\sigma(u; \theta)$. However, not every multivariate diffusion is reducible (a necessary and sufficient condition for reducibility is given in [4]). Whenever a diffusion is reducible, an expansion can be computed for the transition density p_X of X by first computing it for the density p_Y of Y and then transforming Y back into X .

The idea is, in fact, to make two successive transformations $X \mapsto Y \mapsto Z$ such that Z is sufficiently close to a Normal random variable, then construct a sequence for p_Z around a Normal and revert the transformation $Z \mapsto Y \mapsto X$. This will yield an expansion for p_X around a deformed Normal, unless

the volatility function σ is constant (independent of X_t).

When a diffusion is not reducible, the situation is more involved (see the section The Irreducible Case). The expansion for l_Y is of the form

$$l_Y^{(K)}(y|y_0, \Delta; \theta) = -\frac{m}{2} \ln(2\pi \Delta) + \frac{C_Y^{(-1)}(y|y_0; \theta)}{\Delta} + \sum_{k=0}^K C_Y^{(k)}(y|y_0; \theta) \frac{\Delta^k}{k!} \quad (5)$$

The coefficients of the expansion are given explicitly by

$$C_Y^{(-1)}(y|y_0; \theta) = -\frac{1}{2} \sum_{i=1}^m (y_i - y_{0i})^2 \quad (6)$$

$$C_Y^{(0)}(y|y_0; \theta) = \sum_{i=1}^m (y_i - y_{0i}) \int_0^1 \mu_{Yi} \times (y_0 + u(y - y_0); \theta) du \quad (7)$$

and, for $k \geq 1$,

$$C_Y^{(k)}(y|y_0; \theta) = k \int_0^1 G_Y^{(k)}(y_0 + u(y - y_0)|y_0; \theta) u^{k-1} du \quad (8)$$

where $G_Y^{(k)}(y|y_0; \theta)$ is given explicitly as a function of μ_{Yi} and $C_Y^{(j-1)}$, $j = 1, \dots, k$.

Given an expansion for the density p_Y of Y , an expansion for the density p_X of X can be obtained by a direct application of the Jacobian formula:

$$l_X^{(K)}(x|x_0, \Delta; \theta) = -\frac{m}{2} \ln(2\pi \Delta) - D_v(x; \theta) + \frac{C_Y^{(-1)}(\gamma(x; \theta)|\gamma(x_0; \theta); \theta)}{\Delta} + \sum_{k=0}^K C_Y^{(k)}(\gamma(x; \theta)|\gamma(x_0; \theta); \theta) \frac{\Delta^k}{k!} \quad (9)$$

from $l_Y^{(K)}$ given in equation (5), using the coefficients $C_Y^{(k)}$, $k = -1, 0, \dots, K$ given above, and where

$$D_v(x; \theta) \equiv \frac{1}{2} \ln(\text{Det}[v(x; \theta)]) \quad (10)$$

with $v(x; \theta) \equiv \sigma(x; \theta)\sigma^T(x; \theta)$.

The Irreducible Case

In the irreducible case, no such Y exists and the expansion of the log likelihood l_X has the form

$$l_X^{(K)}(x|x_0, \Delta; \theta) = -\frac{m}{2} \ln(2\pi \Delta) - D_v(x; \theta) + \frac{C_X^{(-1)}(x|x_0; \theta)}{\Delta} + \sum_{k=0}^K \times C_X^{(k)}(x|x_0; \theta) \frac{\Delta^k}{k!} \quad (11)$$

The approach is to calculate a Taylor series in $(x - x_0)$ of each coefficient $C_X^{(k)}$, at order j_k in $(x - x_0)$. Such an expansion will be denoted by $C_X^{(j_k, k)}$ at order $j_k = 2(K - k)$, for $k = -1, 0, \dots, K$.

The resulting expansion will then be

$$\tilde{l}_X^{(K)}(x|x_0, \Delta; \theta) = -\frac{m}{2} \ln(2\pi \Delta) - D_v(x; \theta) + \frac{C_X^{(j_{-1}, -1)}(x|x_0; \theta)}{\Delta} + \sum_{k=0}^K \times C_X^{(j_k, k)}(x|x_0; \theta) \frac{\Delta^k}{k!} \quad (12)$$

Such a Taylor expansion was unnecessary in the reducible case: the expressions given above provide the explicit expressions of the coefficients $C_Y^{(k)}$ and then in equation (9) we have the corresponding ones for $C_X^{(k)}$. However, even for an irreducible diffusion, it is still possible to compute the coefficients $C_X^{(j_k, k)}$ explicitly.

For each $k = -1, 0, \dots, K$, the coefficient $C_X^{(k)}(x|x_0; \theta)$ in equation (12) solves an equation of the form

$$f_X^{(k-1)}(x|x_0; \theta) = C_X^{(k)}(x|x_0; \theta) - \sum_{i=1}^m \sum_{j=1}^m \times v_{ij}(x; \theta) \frac{\partial C_X^{(-1)}(x|x_0; \theta)}{\partial x_i} \times \frac{\partial C_X^{(k)}(x|x_0; \theta)}{\partial x_j} - G_X^{(k)}(x|x_0; \theta) = 0 \quad (13)$$

Each function $G_X^{(k)}$, $k = 0, 1, \dots, K$, involves only the coefficients $C_X^{(h)}$ for $h = -1, \dots, k - 1$, so this

system of equation can be utilized to solve recursively for each coefficient at a time. Specifically, the equation $f_X^{(-2)} = 0$ determines $C_X^{(-1)}$, given $C_X^{(-1)}$, $G_X^{(0)}$ becomes known and the equation $f_X^{(-1)} = 0$ determines $C_X^{(0)}$, given $C_X^{(-1)}$ and $C_X^{(0)}$, $G_X^{(1)}$ becomes known and the equation $f_X^{(0)} = 0$ then determines $C_X^{(1)}$, and so on. It turns out that this results in a system of linear equations in the coefficients of the polynomials $C_X^{(j_k, k)}$, so each one of these equations can be solved explicitly in the form of the Taylor expansion $C_X^{(j_k, k)}$ of the coefficient $C_X^{(k)}$, at order j_k in $(x - x_0)$.

Applications: Stochastic Volatility and Term Structure Models

In a stochastic volatility model, the asset price process S_t follows

$$dS_t = (r - \delta)S_t dt + \sigma_1(X_t; \theta) dW_t^Q \quad (14)$$

where r is the riskfree rate, δ is the dividend yield paid by the asset (both taken to be constant only for simplicity), σ_1 denotes the first row of the matrix σ , and Q denotes the equivalent martingale measure [25]. The volatility state variables V_t then follow a stochastic differential equation (SDE) on their own. For example, in the [26] model, $m = 2$ and $q = 1$:

$$dX_t = d \begin{bmatrix} S_t \\ V_t \end{bmatrix} = \begin{bmatrix} (r - \delta)S_t \\ \kappa(\gamma - V_t) \end{bmatrix} dt + \begin{bmatrix} \sqrt{(1 - \rho^2)V_t}S_t & \rho\sqrt{V_t}S_t \\ 0 & \sigma\sqrt{V_t} \end{bmatrix} \times d \begin{bmatrix} W_1^Q(t) \\ W_2^Q(t) \end{bmatrix} \quad (15)$$

The model is completed by the specification of a vector of market prices of risk for the different sources of risk (W_1 and W_2 here), such as

$$\Lambda(X_t; \theta) = \begin{bmatrix} \lambda_1 \sqrt{(1 - \rho^2)V_t} & \lambda_2 \sqrt{V_t} \end{bmatrix}' \quad (16)$$

which characterizes the change of measure from Q back to the physical probability measure P .

Likelihood inference for this and other stochastic volatility models is discussed in [7]. Given a time series of observations of both the asset price, S_t , and a vector of option prices (which, for simplicity,

we take to be call options) C_t , the time series of V_t can then be inferred from the observed C_t . If V_t is multidimensional, sufficiently many options are required with varying strike prices and maturities to allow extraction of the current value of V_t from the observed stock and call prices. Otherwise, only a single option is needed. For reasons of statistical efficiency, we seek to determine the joint likelihood function of the observed data, as opposed to, for example, conditional or unconditional moments. We employ the closed-form approximation technique described above, which yields in closed form the joint likelihood function of $[S_t; V_t]'$. From there, the joint likelihood function of the observations on $G_t = [S_t; C_t]' = f(X_t; \theta)$ is obtained simply by multiplying the likelihood of $X_t = [S_t; V_t]'$ by the Jacobian term J_t :

$$\begin{aligned} \ln p_G(g|g_0, \Delta; \theta) = & -\ln J_t(g|g_0, \Delta; \theta) \\ & + l_X(f^{-1}(g; \theta)|f^{-1} \\ & \times (g_0; \theta); \Delta, \theta) \end{aligned} \quad (17)$$

with l_X obtained as described above.

Another example of practical interest in finance consists of term structure models. A multivariate term structure model specifies that the instantaneous riskless rate r_t is a deterministic function of an m -dimensional vector of state variables, X_t :

$$r_t = r(X_t; \theta) \quad (18)$$

An affine yield model is any model where the short rate (18) is an affine function of the state vector and the risk-neutral dynamics (1) are affine:

$$dX_t = (\tilde{A} + \tilde{B}X_t)dt + \Sigma\sqrt{S(X_t; \alpha, \beta)}dW_t^Q \quad (19)$$

where $\tilde{A}$ is an m -element column vector, $\tilde{B}$ and Σ are $m \times m$ matrices, and $S(X_t; \alpha, \beta)$ is the diagonal matrix with elements $S_{ii} = \alpha_i + X_t' \beta_i$, with each α_i a scalar and each β_i an $m \times 1$ vector, $1 \leq i \leq m$ [19].

It can then be shown that, in affine models, bond prices have the exponential affine form $\exp(-\gamma_0(\tau; \theta) - \gamma(\tau; \theta)'x)$, where $\tau = T - t$ is the bond's time to maturity. Ait-Sahalia and Kimmel [6] consider likelihood inference for affine term structure models on the basis of observations on the bond yields. For other implementations of the method in various contexts and with various datasets [8, 13, 21, 32, 36]. Methods to do small sample bias

corrections, relevant in particular for the speed of mean reversion parameter when near a unit root, are provided by Phillips and Yu [33] and Tang and Chen [35].

Nonlikelihood Methods

Because of the Cramer–Rao lower bound, maximum-likelihood estimation will, at least asymptotically, be efficient and should therefore be the method of choice for estimating θ given that we now have available closed-form, numerically tractable, likelihood expansions. There are, however, a number of alternative methods available to estimate the parameter vector. This discussion will again not include methods appropriate only when the sampling interval Δ tends to 0.

The method of moments is generally not available with standard moments such as the mean, variance, and so on. Hansen and Scheinkman [24] provide moment functions in the form of expectations of the infinitesimal generator that are applied to test functions, while Bibby and Sørensen [9] and Kessler and Sørensen [30] consider other constructions of moment functions.

A different type of moment functions is obtained by simulation. The moment function is the expected value, under the model whose parameters one wishes to estimate, of the score function from an auxiliary model. The idea is that the auxiliary model should be easier to estimate; in particular, the parameters of the auxiliary model appearing in the moment function are replaced by their quasi-maximum likelihood estimates. The parameters of the model of interest are then estimated by minimizing a generalized method of moments (GMM)-like criterion. This method has the advantage of being applicable to a wide class of models. On the other hand, the estimates are obtained by simulations that are computationally intensive and they require the selection of an arbitrary auxiliary model, so the parameter estimates for the model of interest will vary based on both the set of simulations and the choice of auxiliary model. Related implementations of this idea are due to Smith [34], Gouriéroux *et al.* [23], and Gallant and Tauchen [22].

Nonparametric methods are appropriate when the drift and diffusion functions in equation (1) are specified as $\mu(x)$ and $\sigma(x)$ instead of being dependent

upon a finite-dimensional vector of parameters θ . They are particularly useful for the purpose of testing whether a given parametric model for $\mu(x; \theta)$ and $\sigma(x; \theta)$ is appropriate, by comparing the parametric and nonparametric estimates of the corresponding densities.

Let $\pi_X(\cdot, \theta)$ denote the marginal density implied by the parametric model and $p_X(\cdot|\cdot, \cdot, \theta)$ the transition density. Under regularity assumptions, $(\mu(\cdot, \theta), \sigma^2(\cdot, \theta))$ will uniquely characterize the marginal and transition densities over discrete time intervals. For example, the Ornstein–Uhlenbeck process $dX_t = \beta(\alpha - X_t)dt + \gamma dW_t$ generates Gaussian marginal and transitional densities. The square-root process $dX_t = \beta(\alpha - X_t)dt + \gamma X_t^{1/2}dW_t$ yields a Gamma marginal and noncentral chi-squared transitional densities.

More generally, any parametrization of μ and σ^2 corresponds to a parametrization of the marginal and transitional densities. While the direct estimation of μ and σ^2 with discrete data is problematic, the estimation of the densities explicitly takes into account the discreteness of the data. The basic idea in [1] is to use the mapping between the drift and diffusion, on the one hand, and the marginal and transitional densities, on the other, to test the model's specification using densities at the observed discrete frequency (π_X, p_X) instead of the infinitesimal characteristics of the process (μ, σ^2) .

Ait-Sahalia *et al.* [5] develop an alternative specification test for the transition density of the process, based on a direct comparison of the nonparametric estimate of the transition density to the assumed parametric transition function. What makes this new direct testing approach possible is the subsequent development, described above, of closed-form expansions for $p_X(x|x_0, \Delta, \theta)$, which, as already noted, is rarely known in closed form. A complementary approach to this is the one proposed by Hong and Li [27], who use the fact that under the null hypothesis, the random variables $\{P_X(X_{i\Delta}|X_{(i-1)\Delta}, \Delta, \theta)\}$ are a sequence of independent and identically distributed (i.i.d.) uniform random variables [12, 15]. Using for P_X the closed-form approximations described above, they detect the departure from the null hypothesis by comparing the kernel-estimated bivariate density of $\{(Z_i, Z_{i+\Delta})\}$ with that of the uniform distribution on the unit square, where $Z_i = P(X_{i\Delta}|X_{(i-1)\Delta}, \Delta, \theta)$.

Extreme Value Theory

Univariate extreme value theory is primarily concerned with the limiting behavior of *large* (respectively, *small*) values of real-valued random observations $X_1, \dots, X_n$ as the *sample size* n increases indefinitely. We denote this by $n \rightarrow \infty$, bearing in mind that, in applications, n may be as small as 10 or 20. In some models, n may also be random, which brings some added technicalities (see, e.g., § 6.2 in [25]). For example, the number n of *insurance claims* $X_1, \dots, X_n$ observed in a time period is often assumed to follow a *Poisson distribution* independent of the claim sequence [3]. In the following, we let $n \geq 1$ be nonrandom, and denote by

$$X_{1,n} \leq \dots \leq X_{n,n} \quad (1)$$

the *order statistics* of $X_1, \dots, X_n$, obtained by sorting the observations in increasing order. Of interest is the study of the *extreme values* $M_n := X_{n,n} = \max\{X_1, \dots, X_n\}$ and $m_n := X_{1,n} = \min\{X_1, \dots, X_n\}$ as $n \rightarrow \infty$. *Multivariate extreme value theory* concerns observations $\mathbf{X}_1, \dots, \mathbf{X}_n$ in $\mathbb{R}^d$, with *extremal vectors* obtained by taking maxima (or minima) coordinate-wise. We start with the univariate case $d = 1$, before briefly considering extremes in higher dimensions, in the section Multivariate Extremes. We note that the multivariate theory of extreme values relies heavily on the notion of *copula*, which has given rise to intensive research in the last decades [12, 45]. An example of its application to *option pricing* is provided in [34].

The study of limit laws for M_n and m_n is motivated by the quest of *realistic probabilistic models* for *extreme values* of large collections of random variables (rv's). This is inspired by the common practice of statistical science, which often uses asymptotic formulae to approximate finite sample distributions. In the setup of estimation based on *sample means*, rates of convergence to limiting Gaussian laws are of order $O(n^{-1/2})$, which is accurate enough for a number of applications, even when $n = 50$ or less. In extreme value theory, one may obtain convergence rates as slow as $O((\log n)^{-1/2})$, in which case, the limiting theory becomes irrelevant unless the sample size n is huge (see, e.g., [29] and § 2.10 in [25]). Unfortunately, other than the *standard limit laws* discussed in the section Extremes of Independent and Identically

Distributed (IID) Sequences, there are not many alternative models adapted to this situation, especially when not much is known about the data structure. One should therefore always remain *extremely cautious* in the conclusions that may be drawn from a blunt application of extreme value models. This drawback (the *curse of small sample sizes*) turns out here to be one of the major practical difficulties to cope with.

There are two great families of statistical problems dealing with extremes, depending on whether the *sample components* $X_1, \dots, X_n$ are observed or not. In the first case, one infers from $X_1, \dots, X_n$ information concerning the law of M_n (or m_n), and, possibly, on extremes of future observations from analog sequences. This may often be reduced to *tail estimation*, where one evaluates the *tail behavior* of the component distributions out of a selected number of extreme order statistics (see the section Tail Estimation). In the second case, $X_1, \dots, X_n$ are generally unknown, and only extremes generated by these hidden quantities are at hand. Extreme value theory is then used for *model building*, and statistical applications rely on observations of random samples of extreme values. In this case, there are many competing methods of *parametric estimation* for the standard extreme-value distributions (refer to [8, 39], Chapter 19–21 in [35] and Chapter 22 in [36]); however, this problem is not discussed here. We mention that these estimation techniques are always difficult to use in practice, especially for small sample sizes. A major application can be found in *reliability theory* and *lifetime analysis*, where the basic historical references are the books of Barlow and Proschan [1], Crowder *et al.* [10], and Kalbfleisch and Prentice [37].

Univariate extreme values has received considerable attention since the pioneering work of Fréchet [24], Fisher and Tippett [22] and Gnedenko [28], from 1925 to 1945. Somewhat later, between 1935 and 1965, Gumbel [30] illustrated the statistical interest of these methods on a number of natural phenomenon (in particular, *floods*). The probabilistic aspects of the theory made serious progress after 1960. In particular, the contributions of de Haan [13] in the years 1970–1985, through a use of the theory of *slow* and *regular variation*, allowed to fully characterize the domains of attraction of extremal limit laws for independent and identically distributed (i.i.d.) sequences [5, 51]. Other remarkable developments include the point process theory related to *records* and *extremal processes*. These are not considered

here, and we refer to [46] and [49] for details. Multivariate extreme value theory was mostly initiated by Geffroy [27], Sibuya [52], and Tiago de Oliveira [54] during 1958–1960. We refer to [7, 15, 16, 47, 53], and the references therein for more recent contributions. A series of books on the subject are available. We may cite, among others, the monographs, surveys and proceedings volumes [4, 8, 9, 13, 14, 19–21, 23, 25, 26, 39, 40, 48, 55], and [57]. We have not attempted to cite more than a tiny fraction of the thousands of papers of interest, and limit ourselves to a few selected references.

Upper and Lower Extremes

Given an integer $k \geq 1$, the k *upper* (respectively, *lower*) sample *extremes* of $X_1, \dots, X_n$, are denoted by

$$M_n^{(1)} := X_{n,n} \geq \dots \geq M_n^{(k)} := X_{n-k+1,n} \\ \text{(respectively } m_n^{(1)} := X_{1,n} \leq \dots \leq m_n^{(k)} := X_{k,n}) \quad (2)$$

for each $n \geq k$. The (sample) *maximum* and *minimum*, are, respectively given by

$$M_n := M_n^{(1)} = X_{n,n} = \max\{X_1, \dots, X_n\} \quad \text{and} \\ m_n := m_n^{(1)} = X_{1,n} = \min\{X_1, \dots, X_n\} \quad (3)$$

These quantities are of major interest in various fields, especially in economics and finance [3, 14, 19, 21]. For example, when $X_1, \dots, X_n$ denote the successive *claims* registered in an *insurance portfolio*, the upper extremes $M_n^{(1)} \geq M_n^{(2)} \geq \dots$, must be closely monitored to evaluate *reinsurance premiums* [3]. Extreme values are also critical in a number of natural phenomenon, especially when $X_1, \dots, X_n$ are measures of *wind speeds*, *sea levels*, *temperature*, or other environmental indicators of interest [6, 8]. Lower extreme values are essential to *life studies* and *reliability* [1]. In the latter application, $X_1, \dots, X_n$ denote the *life spans* of the n critical components of an equipment. Failure occurs (under the *weakest link principle*, see, e.g., p. 25 in [8]) at time $m_n^{(1)} = \min\{X_1, \dots, X_n\}$. All kind of variants of this basic model are at hand (such as the *k-out-of-n rule*, where the equipment fails when k of its components have stopped functioning (see, e.g., p. 25 in [8]).

In the sequel, we concentrate on *upper extremes*. The description of lower extremes is identical after a scale reversal. Namely, the change of $X_1, \dots, X_n$ into $-X_1, \dots, -X_n$ replaces the upper (respectively, lower) extremes of the first sequence, into (-1) times the lower (respectively, upper) extremes of the second sequence.

Extremes of Independent and Identically Distributed (IID) Sequences

In the *standard* (or i.i.d.) *model* of extreme value theory, $X = X_1, X_2, \dots$ are i.i.d. rv's with distribution function (df) $F(x) = \mathbb{P}(X \leq x)$. Here, $\mathbb{P}(A)$ denotes the probability of the event A . Even though this model may be far from reality (because of departures from the i.i.d. assumption caused by *trends*, *dependence between observations* or *nonidentically distributed components*), it is useful as a *starting point* in a number of real-life applications [8, 39]. The fundamental results of this model are captured into the following facts.

We first seek conditions for the maximum $M_n := M_n^{(1)}$ to have a limiting *nondegenerate* distribution (meaning the law of a nonconstant rv) $G(\cdot)$. This is equivalent to the existence of constants $a_n > 0$ and b_n , $n = 1, 2, \dots$, such that, as $n \rightarrow \infty$

$$\mathbb{P}\left(\frac{M_n - b_n}{a_n} \leq x\right) = F^n(a_n x + b_n) \longrightarrow G(x) \quad (4)$$

for almost all x in $\mathbb{R} := (-\infty, \infty)$. The choice of a_n , b_n , and $G(\cdot)$ in equation (4) being not unique, the limiting $G(\cdot)$, when it exists, is only defined through its *type* (two df's $G_1(\cdot)$ and $G_2(\cdot)$ are of the *same type* iff there are constants $A > 0$ and B fulfilling $G_1(Ax + B) = G_2(x)$ for almost all $x \in \mathbb{R}$).

Fact 1 The limit law (4) holds for some $F(\cdot)$, and appropriate *norming sequences* $a_n > 0$ and b_n iff, up to a *type equivalence* (through the replacement of $G(x)$ by $G((x - \mu)/\sigma)$ for some $\sigma > 0$ and μ), $G(\cdot)$ belongs to the class of *extreme value distributions*, collecting the following df's.

- The *Gumbel* df:

$$G(x) = \Lambda(x) := \exp(-e^{-x}) \quad \text{for } x \in \mathbb{R} \quad (5)$$

- The *Fréchet* (class of) distribution function(s), defined, for $\alpha > 0$ by

$$G(x) = \Phi_\alpha(x) := \begin{cases} \exp(-x^{-\alpha}) & \text{for } x > 0 \\ 0 & \text{for } x \leq 0 \end{cases} \quad (6)$$

- The (reverse) *Weibull* (class of) distribution function(s), defined, for $\alpha > 0$, by

$$G(x) = \Psi_\alpha(x) := \begin{cases} 1 & \text{for } x \geq 0 \\ \exp(-(-x)^\alpha) & \text{for } x < 0 \end{cases} \quad (7)$$

Remark 1 Whenever equation (4) holds, we say that $F(\cdot)$ belongs to the *domain of attraction* of $G(\cdot)$ and write $F \in \mathcal{D}(G)$. An extreme value df, given by (5), (6), or (7), is always of the form $G(x) = \exp(-H(x))$, where $H(x)$ is either exponential (in the Gumbel case), or a power function (in the Fréchet and Weibull cases). In the section, Beyond the Independent and Identically Distributed (IID) Case, this property is extended to nonidentically distributed sequences. In the present setup, (4) holds iff, for all $x \in \mathbb{R}$, as $n \rightarrow \infty$,

$$n(1 - F(a_n x + b_n)) \longrightarrow H(x) \quad (8)$$

Remark 2 In extreme value theory, Fact 1 plays a role of the same importance as the *central limit theorem* (CLT) in “classical” statistics. The CLT leads experimenters to favor the use of *Gaussian* distributions (within the class of *stable* laws) to describe statistics based on *sums* (or *means*) of large numbers of i.i.d. components. In the same spirit, Fact 1, hints that extreme value laws should provide *reasonable candidates* to model the distributions of extremes of large numbers of rv’s. This point is discussed further in the section, Beyond the Independent and Identically Distributed (IID) Case.

Fact 2 The existence of a limiting df $G(\cdot)$, such that $F \in \mathcal{D}(G)$, is, unfortunately, limited to a *relatively small class of smooth distributions* $F(\cdot)$, and applied scientists should not always take it for granted that this property is fulfilled by the data they consider. The characterizations of $\mathcal{D}(\Phi_\alpha)$ and $\mathcal{D}(\Psi_\alpha)$ are simple in terms of the *survivor function* $1 - F(x) = \mathbb{P}(X > x)$ (see, for example, (Φ.1–2) and (Ψ.1–2) below). On the other hand, the characterization

of $\mathcal{D}(\Lambda)$ is a difficult mathematical question, which was only solved, after decades of research, by De Haan [13], Meijzler [43] and Marcus and Pinsky [41], among others, in terms of the *upper quantile function* $U(t) = F^{\text{inv}}(1 - t) = \inf\{x : F(x) \geq 1 - t\}$ for $0 < t < 1$. These results (see equations (11)–(13) below) rely on the notion of *slow variation*. A positive function $L(t)$ defined for $t \geq t_0$ is *slowly varying* (in the neighborhood of infinity) iff, independently of $\lambda > 0$,

$$\lim_{t \rightarrow \infty} \frac{L(\lambda t)}{L(t)} = 1 \quad (9)$$

For example, for $C > 0$ and $r \in \mathbb{R}$, $L(t) = C(\log t)^r$ is slowly varying. Such functions have been used in various branches of mathematics, such as *Tauberian theory* (see, e.g., Chapter V in [56]). Their structure is governed by *Karamata’s theorem* (see [38], and [51]), showing that $L(\cdot)$ fulfills equation (9) iff there exist functions $c(t) \rightarrow c \in (0, \infty)$ and $\epsilon(t) \rightarrow 0$ as $t \rightarrow \infty$, such that, for all $t \geq t_0$,

$$L(t) = c(t) \exp\left(\int_{t_0}^t \frac{\epsilon(u)}{u} du\right) \quad (10)$$

In view of equation (10), we may characterize the domains of attraction of the extreme value laws as follows:

1. $F \in \mathcal{D}(\Phi_\alpha)$ iff F has an infinite upper endpoint $\omega = \sup\{x : F(x) < 1\} = \infty$, and fulfills one of the following equivalent conditions.

(Φ.1) There exists a slowly varying function $L_1(\cdot)$ such that $1 - F(x) = x^{-\alpha} L_1(x)$.

(Φ.2) There exists a slowly varying function $\ell_1(\cdot)$ such that $U(t) = t^{-1/\alpha} \ell_1(1/t)$ ($0 < t < 1$).

The df’s $F(\cdot)$ fulfilling (Φ.1) compose the class of *Pareto-type* laws, which is of major importance in applications of extreme value theory to distributions with infinite upper endpoints.

2. $F \in \mathcal{D}(\Psi_\alpha)$, iff F has a finite upper endpoint $\omega = \sup\{x : F(x) < 1\} < \infty$, and fulfills one of the following equivalent conditions.

(Ψ.1) There exists a slowly varying function $L_2(\cdot)$ such that $1 - F(\omega - x) = x^\alpha L_2(1/x)$ ($x > 0$).

- (Ψ.2) There exists a slowly varying function $\ell_2(\cdot)$ such that $U(t) = \omega - t^{1/\alpha} \ell_2(1/t)$ ($0 < t < 1$).
3. $F \in \mathcal{D}(\Lambda)$ for distributions with arbitrary upper endpoint, iff, the following condition holds.
- (Λ) There exists a slowly varying function $\ell_3(\cdot)$ such that, for each $r > 0$, as $t \downarrow 0$,

$$U(rt) - U(t) = -(1 + o(1))(\log r) \ell_3(1/t) \quad (11)$$

The conditions (Φ.1)–(Φ.2), (Ψ.1)–(Ψ.2) and (Λ), may be combined as follows [13]. The existence of $G \in \{\Phi_\alpha, \Psi_\alpha, \Lambda\}$ such that $F \in \mathcal{D}(G)$ is equivalent to the existence (in $\mathbb{R}$) of the limit, for all $r > 0$ and $s > 0$ with $s \neq 1$,

$$L(r, s) = \lim_{t \downarrow 0} \frac{U(rt) - U(t)}{U(st) - U(t)} \quad (12)$$

Whenever it exists, the limit in equation (12) can only be of the form $L_\gamma(r, s)$, for some $\gamma \in \mathbb{R}$, where

$$L(r, s) = L_\gamma(r, s) := \frac{r^{-\gamma} - 1}{s^{-\gamma} - 1} \quad \text{when } \gamma \neq 0 \quad (13)$$

or

$$L(r, s) = L_0(r, s) := \frac{\log r}{\log s} \quad (14)$$

The constant $\gamma \in \mathbb{R}$ is usually called the *extremal index* pertaining to $F(\cdot)$ (or $U(\cdot)$). We have the following equivalent statements:

$$\gamma > 0 \iff F \in \mathcal{D}(\Phi_\alpha) \quad \text{with } \alpha = 1/\gamma \quad (15)$$

$$\gamma < 0 \iff F \in \mathcal{D}(\Psi_\alpha) \quad \text{with } \alpha = -1/\gamma \quad (16)$$

$$\gamma = 0 \iff F \in \mathcal{D}(\Lambda) \quad (17)$$

Remark 3 As follows from Fact 2, a *serious amount of smoothness* is needed for a df $F(\cdot)$ to belong to $\mathcal{D}(G)$ for some $G(\cdot)$. This is especially the case for $\mathcal{D}(\Lambda)$ and somewhat less for $\mathcal{D}(\Phi_\alpha)$ and $\mathcal{D}(\Psi_\alpha)$. A number of *standard distributions* of the literature fulfill the appropriate conditions, but there are some notable exceptions (in particular for the discrete df's, as mentioned below). Also, one should observe that the *standard* continuous distributions of

statistics [35, 36] are always *extremely smooth*, and this property may not be shared by *real-life* distributions originating from experimental data. Therefore, one should always keep in mind that *the basic assumptions needed for extreme value models are not likely to be fulfilled by real-life observations*. For example, distributions $F(\cdot)$ with $U(1/t)$ slowly varying as $t \rightarrow \infty$ do not necessarily fulfill (Λ), and may very well not belong to $\mathcal{D}(\Lambda)$. This illustrates the fact that *the use of Gumbel laws to model extremal data is often problematic*. For standard distributions, the situation is more clear cut, as follows [35, 36]:

- All *standard continuous* df's $F(\cdot)$ of interest *do belong to $\mathcal{D}(G)$ for some $G \in \{\Lambda, \Phi_\alpha, \Psi_\alpha\}$* . In particular, upper extremes of smooth *exponential-tailed* distributions, such as the exponential, gamma, normal, lognormal, and Weibull laws, belong to the domain of attraction $\mathcal{D}(\Lambda)$ of the Gumbel law. The Fréchet $\mathcal{D}(\Phi_\alpha)$ domain holds for distributions with polynomial-type tails, such as *exact Pareto laws* of the form $1 - F(x) = C(x - a)^{-\alpha}$ for $x \geq x_0 > a$, which are special cases of (Φ.1). Another important example of distributions in the Fréchet domain $\mathcal{D}(\Phi_\alpha)$ is given by the non-Gaussian *stable laws*. The case of the (reverse) Weibull law Ψ_α is somewhat similar to Φ_α , and is not discussed here.
- Almost all *standard discrete* df's $F(\cdot)$ of interest *do not belong to $\mathcal{D}(G)$ for any possible $G \in \{\Lambda, \Phi_\alpha, \Psi_\alpha\}$* . For example, the upper extremes of Poisson, geometric, or negative binomial distributions are not in the domain of attraction of an extreme value law. This disappointing fact brings some obvious practical difficulties, since all possible data sets are given on discrete scales.
- Whenever the upper endpoint $\omega := \sup\{x : F(x) < 1\}$ of the distribution $F \in \mathcal{D}(G)$ is *finite*, the only possible choice for $G(\cdot)$ is either Weibull Ψ_α or Gumbel Λ .
- Whenever the upper endpoint $\omega := \sup\{x : F(x) < 1\}$ of the distribution $F \in \mathcal{D}(G)$ is *infinite*, the only possible choice for $G(\cdot)$ is either Fréchet Φ_α or Gumbel Λ .

Remark 4 Because of Fact 2, the study of upper extremes for *unbounded* distributions may be limited to df's $F(\cdot)$ belonging to the Fréchet and Gumbel domains of attraction, with a nonnegative extremal index $\gamma \geq 0$. In the sequel, we concentrate on this case, which is the most relevant for financial

models. Our point of view would be different if we had been concerned with *reliability theory*, for which the underlying distributions are bounded below by 0 (since the lifetime of a component cannot be negative). For this reason, the (direct or usual) Weibull distributions (including the exponential law) have become reference models for lifetime distributions. These laws correspond to $\gamma \leq 0$. We note that the standard form of a Weibull survival time T is obtained by changing signs in equation (7), so that (after some proper changes of scale and origin) $\mathbb{P}(T > t) = \exp(-t^\alpha)$ for $t > 0$ and some $\alpha > 0$. The special case $\alpha = 1$ yields the *exponential law*, which appears as the foremost example of extreme value law for minima.

Fact 3 The constants a_n and b_n in equation (4) can be chosen as follows. Recall the definition $U(t) = F^{\text{inv}}(1 - t) := \inf\{x : F(x) \geq 1 - t\}$ for $0 < t < 1$ of the *upper quantile function* of F .

- When $F \in \mathcal{D}(\Phi_\alpha)$, we may set $a_n = U(1/n)$ and $b_n = 0$ in equation (4), so that, as $n \rightarrow \infty$,

$$\mathbb{P}\left(\frac{M_n}{a_n} \leq x\right) \longrightarrow \Phi_\alpha(x) = \exp(-x^{-\alpha}) \quad \text{for } x > 0 \quad (18)$$

- When $F \in \mathcal{D}(\Lambda)$, we may set $a_n = U(1/(ne)) - U(1/n)$ and $b_n = U(1/n)$ in equation (4).

Remark 5 As a consequence of the results above, when $F \in \mathcal{D}(\Phi_\alpha)$, we have, for some slowly varying function $L_0(\cdot)$, the convergence in distribution, as $n \rightarrow \infty$

$$\frac{M_n}{n^{1/\alpha} L_0(n)} \xrightarrow{d} \Phi_\alpha \quad (19)$$

This implies a *very fast rate of increase* for M_n as $n \rightarrow \infty$, especially when $0 < \alpha < 1$, in which case, it may be shown (see, e.g., §4.5 in [25]) that the sample sum $X_1 + \dots + X_n$ and maximum $\max\{X_1, \dots, X_n\}$ have the same order of magnitude. On the other hand, when $F \in \mathcal{D}(\Lambda)$, we have, for any choice of $\alpha > 0$ and $L_0(\cdot)$, the convergence in probability, as $n \rightarrow \infty$

$$\frac{M_n}{n^{1/\alpha} L_0(n)} \xrightarrow{\mathbb{P}} 0 \quad (20)$$

This has important practical consequences. In many real-life examples, the data sets are *mixtures*

of rv's with different distributions. For example, in an insurance portfolio, it is often the case that the central part of the claim distribution is well fitted with a *lognormal distribution*. The exceptions, when they occur, are mostly in the upper tails, where one often detects a small proportion of *outliers* [2], which cannot fit into the lognormal model. When such a phenomenon occurs, it should be interpreted as the presence in the data set of a *Pareto-type* component (fulfilling $(\Phi.1)$), by definition, in the domain of attraction of a Fréchet law [50]. What one should do then is to perform some tail-estimation procedure on the outlying data. This, however, is always problematic, especially if the number of outliers (or identified as such) is relatively small. On the other hand, the presence of Pareto-type claims in a portfolio may generate huge losses if they are not properly taken into account.

Fact 4 In the standard model, the limiting behavior of the maximum $M_n = M_n^{(1)}$ governs the joint limiting behavior of any fixed number $k \geq 1$ of upper extremes $M_n^{(1)}, \dots, M_n^{(k)}$. More specifically, for each fixed $k \geq 1$, the existence of a nondegenerate limiting distribution $G(\cdot)$ for the maximum $M_n^{(1)}$ fulfilling equation (4) is equivalent to the existence of a limiting joint distribution for any (nonempty) subset of the $k \geq 1$ upper extremes $M_n^{(1)}, \dots, M_n^{(k)}$. In particular, equation (4) holds if and only if, for each $x_1, \dots, x_k \in \mathbb{R}$, as $n \rightarrow \infty$,

$$\mathbb{P}\left(\frac{M_n^{(1)} - b_n}{a_n} \leq x_1, \dots, \frac{M_n^{(k)} - b_n}{a_n} \leq x_k\right) \longrightarrow G_k(x_1, \dots, x_k) \quad (21)$$

where G_k is a nondegenerate multivariate distribution depending only upon G and $k \geq 1$. Its structure is of major interest, and is detailed below. First, we consider the k th maximum, for an arbitrary (but fixed) $k \geq 1$. Let $G(x) = \exp(-H(x))$ in equation (4). This statement is equivalent to having, for each specified $k \geq 1$ and all $x \in \mathbb{R}$, as $n \rightarrow \infty$,

$$\mathbb{P}\left(\frac{M_n^{(k)} - b_n}{a_n} \leq x\right) \longrightarrow \left\{ \sum_{j=0}^{k-1} \frac{H(x)^j}{j!} \right\} \times \exp(-H(x)) \quad (22)$$

It is convenient to define the inverse function of $H(x) = -\log G(x)$ by $H^{\text{inv}}(t) = \inf\{x : H(x) \geq t\}$

Table 1 Scaling functions for extreme value laws

Extreme value law	$G(x)$	$H(x)$	$H^{\text{inv}}(t)$
Gumbel	$\Lambda(x)$	e^{-x} for $x \in \mathbb{R}$	$-\log t$ for $t > 0$
Fréchet	$\Phi_\alpha(x)$	$x^{-\alpha}$ for $x > 0$	$t^{-1/\alpha}$ for $t > 0$
Weibull	$\Psi_\alpha(x)$	$(-x)^{-\alpha}$ for $x < 0$	$-t^{-1/\alpha}$ for $t > 0$

for $t > 0$. We obtain the particular cases given in Table 1.

In view of Table 1, we may give an explicit form for the limit law in equation (21). Denote by $\omega_1, \omega_2, \dots$ i.i.d. exponential rv's with mean 1. In other words, $\mathbb{P}(\omega_j > y) = e^{-y}$ for $y \geq 0$. Then, for each specified $k \geq 1$, we have the convergence in distribution, as $n \rightarrow \infty$,

$$\left\{ \frac{M_n^{(1)} - b_n}{a_n}, \dots, \frac{M_n^{(k)} - b_n}{a_n} \right\} \xrightarrow{d} \{H^{\text{inv}}(\omega_1), \dots, H^{\text{inv}}(\omega_1 + \dots + \omega_k)\} \quad (23)$$

Remark 6 This result has the important consequence that (in the standard model, subject to $F \in \mathcal{D}(G)$), for each fixed $k \geq 1$, the limiting structure of the k upper extremes depends only upon $G(x) = \exp(-H(x))$ through the nonlinear change of scale $t \rightarrow H^{\text{inv}}(t)$.

Remark 7 The fact that the Gumbel class is a boundary case between the Fréchet and Weibull laws becomes straightforward when $\Lambda, \Phi_\alpha, \Psi_\alpha$ are united into the class of *generalized extreme value* (GEV) laws. The latter, in standard form, depend only upon the *extreme value index* γ (or *shape parameter*) through

$$G_\gamma(x) = \begin{cases} \exp(-(1 + \gamma x)^{1/\gamma}) & \text{for } 1 + \gamma x > 0 \text{ and } \gamma \neq 0 \\ \exp(-e^{-x}) & \text{for } x \in \mathbb{R} \text{ and } \gamma = 0 \end{cases} \quad (24)$$

In the GEV setup, G_γ is of Weibull $\Psi_{-1/\gamma}$ type when $\gamma < 0$, of Fréchet $\Phi_{1/\gamma}$ type when $\gamma > 0$, and Gumbel Λ type when $\gamma = 0$. The representation of extreme value laws through Λ, Φ_α , and Ψ_α with $\alpha > 0$, or through G_γ with $\gamma \in \mathbb{R}$ is a matter of pure convenience, and corresponds to identical

models. In each case, an extreme value distribution is characterized by the extremal index (also called the *shape parameter*) γ , and by centering and scale factors μ and $\sigma > 0$. The general form of $G(\cdot)$ in equation (4) is therefore given by

$$G(x) = G_\gamma \left(\frac{x - \mu}{\sigma} \right) \quad (25)$$

where G_γ is as in equation (24). The GEV model has the advantage of characterizing an extreme value distribution through the triplet of parameters $\gamma \in \mathbb{R}$, $\mu \in \mathbb{R}$, and $\sigma > 0$.

Beyond the Independent and Identically Distributed (IID) Case

The simplest variant of the standard model of the section, Extremes of Independent and Identically Distributed (IID) Sequences, is when $X_1, X_2, \dots$ are independent but nonidentically distributed. Setting $F_j(x) = \mathbb{P}(X_j \leq x)$ for $j = 1, 2, \dots$, the corresponding version of equation (4) is given by

$$\mathbb{P} \left(\frac{M_n - b_n}{a_n} \leq x \right) = \prod_{j=1}^n F_j(a_n x + b_n) \longrightarrow G(x) \quad (26)$$

If no further assumption is made, then the asymptotic theory based upon equation (26) is rather disappointing, since any given df $G(\cdot)$ may be the limit law of $(M_n - b_n)/a_n$ for some suitable b_n and $a_n > 0$, subject to the proper choice of $F_1, F_2, \dots$ [33]. It is natural to impose some additional *uniformity assumptions* (see, e.g., § 3.10 in [25]) implying, in particular, that the limiting law in equation (26) is unaffected by deleting one component of the sequence. If so, setting $G(x) = \exp(-H(x))$, in view of equation (8), we see that equation (26) (subject to the uniformity assumptions) is equivalent to

$$\sum_{j=1}^n (1 - F_j(a_n x + b_n)) \longrightarrow H(x) \quad (27)$$

In this case (see, e.g., § 3.9 in [25]), the class of $H(\cdot)$ on the right-hand side of equation (27) is limited to the functions fulfilling one among the following conditions.

1. $H(\cdot) = -\log G(\cdot)$ is convex.
2. The upper endpoint $\omega_G := \sup\{x : G(x) < \infty\}$ of $G(\cdot)$ is finite and $H(\omega_G - e^{-x})$ is convex.
3. The lower endpoint $a_G := \inf\{x : G(x) > 0\}$ of $G(\cdot)$ is finite and $H(a_G + e^x)$ is convex.

It follows that (1) holds when $G(x) = \Lambda(x)$, since $H(x) = e^{-x}$ is convex. When $G(x) = \Phi_\alpha(x)$, we have $a_G = 0$ and $H(x) = x^\alpha$. In this case, (3) holds, since $H(e^x) = e^{-\alpha x}$ is convex. A similar result holds for $G(x) = \Psi_\alpha(x)$, which is covered by (2).

At this point, we reach the unpleasant conclusion that *some slight variations in the assumption that the sample components are identically distributed may result in extremes with distributions far away from the classical triplet Φ_α , Ψ_α , and Λ of the section Extremes of Independent and Identically Distributed (IID) Sequences*. Recalling Remark (2), we may compare this with the *erroneous belief* (which is quite common among nonexpert statisticians) that most distributions generated by sums of random components should be close to Gaussian laws. Any serious applied scientist knows quite well that this is very often untrue. Moreover, there is no such thing as a *perfect Gaussian sample*, even when it comes from simulated data. In the same spirit, there is no such thing as a *perfect extreme-value sample*, in the sense that, on real-life data sets, Φ_α , Ψ_α , and Λ provide, at best, some rough approximations of some more complex unknown distributions. There is no general recipe available in the scientific literature to *go beyond* extreme value laws, and one must, therefore, proceed with care in the interpretation of data by extreme value laws, in particular, by using *nonparametric methods* when the sample size allows their application.

There is a very important literature on extremes generated by *dependent sequences*. We refer to [25] for details on exchangeable and related models, and to [40] for a general treatment of extremes generated by various types of stochastic processes, such as stationary sequences. As far as financial time series are concerned, the recent review [44] is most useful. It turns out that, under rather weak *tail-mixing conditions*, measuring the asymptotic independence of random components, subject to the fact that they

are simultaneously large and with indices far from each other, most of the results of the standard case still apply. This is even true for *tail estimators* [32]. Extremes generated by *continuous processes* tend to be much more complex than those that we have been considering up to now for integer-indexed sequences. For this reason, this question is not discussed here. The case of *Gaussian processes* has been extensively explored, and we refer to [40] for an advanced initiation to this problem.

Tail Estimation

We limit ourselves to the case where the upper endpoint $\omega = \sup\{x : F(x) < 1\}$ of the df F is infinite ($\omega = \infty$), and where F is in the domain of attraction of an (upper) extreme value distribution. As discussed in the section Upper and Lower Extremes we have, either $F \in \mathcal{D}(\Lambda)$, or $F \in \mathcal{D}(\Phi_\alpha)$ for some $\alpha > 0$. Since the Gumbel law Λ is the limit of Φ_α when $\alpha \rightarrow \infty$, we set, for convenience, $\Lambda = \Phi_\infty$, and assume that $F \in \mathcal{D}(\Phi_\alpha)$ for some $\alpha \in (0, \infty]$. The problem is then to estimate the *regular variation index* $\alpha > 0$, or equivalently, the *tail index* $\gamma = 1/\alpha \in [0, \infty)$, out of $X_1, \dots, X_n$. In the following, we restrict our study to $\gamma \in (0, \infty)$, for Pareto-type laws, fulfilling, as $x \rightarrow \infty$,

$$1 - F(x) = x^{-1/\gamma} L_1(x) = x^{-1/\gamma} L_1(x) \quad (28)$$

where $L_0(\cdot)$ is a slowly varying function. The modern approach to this problem was initiated in 1975 by Hill [31], who introduced the estimator

$$\begin{aligned} \hat{\gamma}_n &= \frac{1}{k} \sum_{j=1}^k \left\{ \log X_{n-j+1,n} - \log X_{n-k,n} \right\} \\ &= \sum_{j=1}^k \frac{j}{k} \left\{ \log X_{n-j+1,n} - \log X_{n-j,n} \right\} \end{aligned} \quad (29)$$

where $1 \leq k = k_n < n$ is an integer sequence varying with n . The use of $\hat{\gamma}_n$ is motivated by its *optimal character* as an estimator of γ based upon the k upper extremes $\{X_{n-j+1,n} : 1 \leq j \leq k+1\}$, in the particular case where $F(x) = 1 - x^{-\alpha}$ for $x \geq 1$, follows an *exact* Pareto law. Moreover, the *Hill estimator* remains consistent under equation (28) subject to minimal conditions imposed upon k_n . This was proved in 1982 by Mason [42]

(see also Deheuvels *et al.* [17]), who showed that the conditions $k = k_n \rightarrow \infty$ and $k_n/n \rightarrow 0$ are *necessary and sufficient* for the convergence (in probability) of γ_n to γ as $n \rightarrow \infty$ for all $F \in \mathcal{D}(\Phi_{1/\gamma})$. For an *exact Pareto law*, these conditions also imply the asymptotic normality of $\hat{\gamma}_n$, which fulfills the convergence in distribution (with $N(0, 1)$ denoting the standard normal law), as $n \rightarrow \infty$,

$$\sqrt{k_n} \left\{ \frac{\hat{\gamma}_n}{\gamma} - 1 \right\} \xrightarrow{d} N(0, 1) \quad (30)$$

Unfortunately, with the exception of the special case of exact Pareto laws, the Hill estimator is always *biased*, and problematic to use. Besides the choice of the origin (to allow the definition of the logarithms in equation 29), the selection of $k = k_n$ is quite delicate. This was illustrated in a number of papers where the performance of the Hill estimator was investigated on simulated and real data sets [3, 50], with different choices of k . At times, the results are so poor that these graphs have been called *Hill horror plots*. Hill's estimator as well as a number of alternative estimators of γ fall into the general class of *Kernel estimators* introduced in 1985 by Csörgő *et al.* [11]. These require a nonincreasing kernel $K(t) \geq 0$ on $[0, 1]$ and are defined by

$$\begin{aligned} \tilde{\gamma}_n = & \left(\sum_{j=1}^k \frac{j}{k} K\left(\frac{j}{k}\right) \{\log X_{n-j+1,n} - \log X_{n-j,n}\} \right) \\ & \times \left(\sum_{j=1}^k \frac{1}{k} K\left(\frac{j}{k}\right) \right)^{-1} \end{aligned} \quad (31)$$

Hill's estimator is the special case of equation (31) obtained by choosing $K(t) = 1$ for $0 \leq t \leq 1$. As seen from the results of [11], the optimality of Hill's estimator is restricted to exact Pareto laws. An interesting application is given when $\tilde{\gamma}_n$ is applied to non-Gaussian *stable laws*. It turns out that in this case, the optimal choice of $K(\cdot)$ is given by $K(t) = 1 - t$ for $0 \leq t \leq 1$, and the optimal choice of k_n is of the form $Rn^{1/3}$ for some appropriate constant R . This illustrates again the *curse of small sample sizes*. For example, when $n = 1000$, which is a rather large sample, we get $n^{1/3} = 10$. It is then rather difficult to admit that such a small value should fall within the range of $k_n \rightarrow \infty$.

In applied science, tail estimation is a mix between know-how and advanced mathematics. The latter provides nice limit laws, with assumptions which are, more or less, never really fulfilled by the data of interest. At this point, an expert opinion becomes closer to a fancy guess than a seriously established scientific fact. We omit a detailed discussion of the various methods in use [3, 8, 14, 18, 19, 21, 39].

Multivariate Extremes

For convenience, we limit our exposition to an i.i.d. sequence $(X_1, Y_1), \dots, (X_n, Y_n)$ of random vectors in $\mathbb{R}^2$. We are concerned with the limiting behavior of $(U_n, V_n) := (\max\{X_1, \dots, X_n\}, \max\{Y_1, \dots, Y_n\})$ as $n \rightarrow \infty$, assuming the existence of sequences of constants $a'_n > 0$, $a''_n > 0$, b'_n and b''_n such that, as $n \rightarrow \infty$,

$$\mathbb{P}\left(\frac{U_n - b'_n}{a'_n} \leq x, \frac{V_n - b''_n}{a''_n} \leq y\right) \longrightarrow G(x, y) \quad (32)$$

Here, $G(\cdot, \cdot)$ denotes a bivariate df with nondegenerate marginal df's $K_1(x) = G(x, \infty)$ and $K_2(y) = G(\infty, y)$. This implies that K_1 and K_2 belong to the class $\{\Phi_\alpha, \Psi_\alpha, \Lambda : \alpha > 0\}$ of extreme value laws. This, however, is not enough. The *copula function* $C(\cdot, \cdot)$ of $G(\cdot, \cdot)$ defined through the identity

$$G(x, y) = C(K_1(x), K_2(y)) \quad (33)$$

must belong to the class of *extreme value copulas*. As shown by Pickands [47], the characterization of a bivariate extreme value copula reduces to a convex function $\{D(x) : x \in [0, 1]\}$ fulfilling the inequalities $\max\{x, 1 - x\} \leq D(x) \leq 1$. Several nonparametric estimation procedures have been proposed ([7, 16, 53, 57], and, for example, Chapter 3 [39]) to estimate $D(\cdot)$, which is often called the *dependence function* (even though this denomination is ambiguous, having been used with other meanings) of $G(\cdot, \cdot)$. This is a very active research field at the present time. The situation in higher dimensions ($d \geq 3$) is even more complex, and has not yet led to very practical solutions.

Conclusion

Extreme value theory is a fascinating mathematical domain, which is often rather difficult to apply to real-life experiments, mostly because it relies on *tail properties* of the underlying distributions, for which very few observations are available. One should therefore always keep in mind, in this domain, the general principle that *statistical conclusions are always limited by the information carried by the data itself*. When this information is sparse or not available, scientists should remain careful about its interpretation.

GARCH Models

Univariate Models of Conditional Heteroskedasticity

The ARCH Model

Financial economists are concerned with modeling and forecasting volatility in asset returns. This is the case since volatility is considered a measure of risk, and investors want a premium for investing in risky assets. Marginal distributions of typical return series have heavy tails, and the series show clustering of volatility. Furthermore, these series have little or no autocorrelation, but they do display higher order dependence. For example, the squared returns are positively autocorrelated. The autoregressive conditional heteroskedasticity (ARCH) model and its variants have been found useful in describing data with these properties.

The original ARCH model, introduced by Engle [21], can be defined as follows. Let ε_t be a random variable that has a mean and a variance conditionally on the information set $\mathcal{F}_{t-1}$ that contains all past information up until $t - 1$ and available at time t . The ARCH model of ε_t has the following properties. First, the conditional mean $\mathbf{E}\{\varepsilon_t|\mathcal{F}_{t-1}\} = 0$ and, second, the conditional variance $h_t = \mathbf{E}\{\varepsilon_t^2|\mathcal{F}_{t-1}\}$ is a nontrivial positive-valued parametric function of $\mathcal{F}_{t-1}$. The sequence $\{\varepsilon_t\}$ may be observed directly. In that case it may be, for example, a sequence of daily returns of an asset or an index. It may also be an unobserved error or innovation sequence of an econometric model. In the latter case,

$$\varepsilon_t = y_t - \mathbf{E}\{y_t|\mathcal{F}_{t-1}\} \quad (1)$$

where y_t is an observable random variable and $\mathbf{E}\{y_t|\mathcal{F}_{t-1}\}$ is the conditional mean of y_t given $\mathcal{F}_{t-1}$. Here, the focus is on h_t and it is assumed that $\mathbf{E}\{y_t|\mathcal{F}_{t-1}\} = 0$.

Engle assumed that ε_t can be decomposed as follows:

$$\varepsilon_t = z_t h_t^{1/2} \quad (2)$$

where $\{z_t\}$ is a sequence of independent, identically distributed (iid) random variables with zero mean and unit variance. This implies $\varepsilon_t|\mathcal{F}_{t-1} \sim \mathcal{D}(0, h_t)$ where $\mathcal{D}$ stands for a distribution, assumed to be

either a normal distribution or a leptokurtic one, such as the t -distribution. The information set $\mathcal{F}_{t-1} = \{\varepsilon_{t-j} : j \geq 1\}$. The conditional variance of an ARCH model of order q has the following parametric form:

$$h_t = \alpha_0 + \sum_{j=1}^q \alpha_j \varepsilon_{t-j}^2 \quad (3)$$

where $\alpha_0 > 0$, $\alpha_j \geq 0$, $j = 1, \dots, q - 1$, and $\alpha_q > 0$.

The parameter restrictions in equation (3) form a necessary and sufficient condition for positivity of the conditional variance. Suppose the unconditional variance $\mathbf{E}\varepsilon_t^2 = \sigma^2 < \infty$. The definition of ε_t through the decomposition (2) involving z_t then guarantees the white noise property of the sequence $\{\varepsilon_t\}$, since $\{z_t\}$ is a sequence of iid variables. In fact, the ARCH model can be viewed as a special case of the family of models with uncorrelated observations but higher order dependence, such that the squared observations are correlated.

The ARCH model and its generalizations are applied to modeling, among other things, high-frequency data on interest rates, exchange rates and stock and stock index returns. “High frequency” in this context means weekly, daily, or intradaily observations. Bollerslev *et al.* [12] already listed a large variety of applications in their survey of these models, and their number has increased enormously since then. Forecasting volatility of these series is different from forecasting the conditional mean of a process because volatility, the object to be forecast, is not observed. The question then is how volatility should be measured. Using ε_t^2 is an obvious solution, but it is not necessarily a good one if data of higher frequency are available. Andersen and Bollerslev [3] and others recommend *realized volatility* (see **Realized Volatility and Multipower Variation**) for the purpose; for a review see [2].

The Generalized ARCH Model and Extensions

Generalized ARCH. The ARCH model has since been extended by adding lagged conditional variances to equation (3). This extension, called the *generalized ARCH (GARCH) model*, proposed independently by Bollerslev [10] and Taylor [67], has since become very popular. The GARCH(p, q) model has the

following form:

$$h_t = \alpha_0 + \sum_{j=1}^q \alpha_j \varepsilon_{t-j}^2 + \sum_{j=1}^p \beta_j h_{t-j} \quad (4)$$

A sufficient condition for the conditional variance h_t in equation (4) to be positive is $\alpha_0 > 0$, $\alpha_j \geq 0$, $j = 1, \dots, q$; $\beta_j \geq 0$, $j = 1, \dots, p$. This condition is not necessary if either p or q , or both, exceed 1; see [56]. For the GARCH model to be identified if at least one $\beta_j > 0$ (the model is a genuine GARCH model), it is required that also at least one $\alpha_j > 0$. If $\alpha_1 = \dots = \alpha_q = 0$, the conditional and unconditional variances of ε_t are equal and $\beta_1, \dots, \beta_p$ are unidentified nuisance parameters. The GARCH(p, q) process is weakly stationary if and only if $\sum_{j=1}^q \alpha_j + \sum_{j=1}^p \beta_j < 1$.

The overwhelmingly most frequently applied GARCH model has been the GARCH(1,1) model. The weakly stationary GARCH(1,1) model only contains three parameters, but one more parameter can be saved by “variance targeting”. The idea is to replace the intercept α_0 in equation (4) by $(1 - \alpha_1 - \beta_1)\sigma^2$ where $\sigma^2 = E\varepsilon_t^2$. The estimate $\hat{\sigma}^2 = T^{-1} \sum_{t=1}^T \varepsilon_t^2$ is substituted for σ^2 before estimating the other two parameters. As a result, the conditional variance converges toward the “long-run” unconditional variance, which may be considered a desirable property of the model.

Since its introduction, the GARCH model has been generalized and extended in various directions. This has been done in order to increase the flexibility of the original model. Because it only contains squared lags of ε_t , the response of the conditional variance to a shock ε_t is independent of the sign of the shock and just a function of its size. Several extensions of the GARCH model aim at accommodating the asymmetry in the response, caused by the *leverage effect* present in stock returns. The most frequently applied asymmetric GARCH model is the GJR-GARCH model of [32]. It is defined as follows:

$$h_t = \alpha_0 + \sum_{j=1}^q \{\alpha_j + \delta_j I(\varepsilon_{t-j} > 0)\} \varepsilon_{t-j}^2 + \sum_{j=1}^p \beta_j h_{t-j} \quad (5)$$

where $I(\varepsilon_{t-j} > 0)$ is an indicator function obtaining value 1 when the argument is true and 0 otherwise. The asymmetry in the data is modeled through the terms $\delta_j I(\varepsilon_{t-j} > 0) \varepsilon_{t-j}^2$, $j = 1, \dots, q$, in equation (5). Typically, in applications, $p = q = 1$. Other asymmetric GARCH models include the asymmetric GARCH (AGARCH) of [27] and the quadratic GARCH of [59]. Furthermore, the smooth transition GARCH (STGARCH) model, introduced by Hagerud [38] and Gonzalez-Rivera [33], can be used for describing asymmetries in return series. This model contains a continuum of regimes, whereas in the GJR-GARCH(1,1) model there are only two regimes with the switch point at $\varepsilon_t = 0$. The GJR-GARCH model is still linear in parameters, which makes it easier to estimate than, say, the STGARCH model that is genuinely nonlinear in parameters.

There are other nonlinear GARCH models that have been applied in practice. Perhaps the most prominent example is the Markov-switching GARCH model. It contains a finite number (usually two) of regimes, and the GARCH process switches between them according to a latent random variable. It was originally introduced as an ARCH model (see [16] and [39]) and is in that form defined as follows:

$$h_t = \sum_{i=1}^k \left(\alpha_0^{(i)} + \sum_{j=1}^q \alpha_j^{(i)} \varepsilon_{t-j}^2 \right) I(s_t = i) \quad (6)$$

where s_t is the discrete latent random variable obtaining values from the set $S = \{1, \dots, k\}$ of regime indicators. It follows a (usually first-order) homogeneous Markov chain:

$$\Pr\{s_t = j | s_t = i\} = p_{ij}, \quad i, j = 1, \dots, k \quad (7)$$

hence the name Markov-switching GARCH. The transition probabilities p_{ij} are parameters to be estimated. An argument put forward to motivate the use of these models is that they can be applied in situations where the conditional variance process contains breaks, that is, sudden changes in parameters. Augmenting the ARCH form (6) by lags of the conditional variance causes estimation problems; see [35, 42] and [37] for discussion and solutions.

Modeling the Conditional Standard Deviation. Models for the conditional variance constitute the most popular way of modeling conditional heteroskedasticity. Similar models, however, have also

been constructed for the conditional standard deviation. By replacing h_t in equation (4) by $h_t^{1/2}$, h_{t-j} by $h_{t-j}^{1/2}$, $j = 1, \dots, p$, and ε_{t-j}^2 by $|\varepsilon_{t-j}|$, $j = 1, \dots, q$, one obtains the absolute-valued GARCH model. Doing this in the GJR-GARCH model yields the threshold GARCH (TGARCH) model that [71] considered. The TGARCH(p, q) model is usually parameterized somewhat differently from the GJR-GARCH model:

$$h_t^{1/2} = \alpha_0 + \sum_{j=1}^q (\alpha_j^+ \varepsilon_{t-j}^+ - \alpha_j^- \varepsilon_{t-j}^-) + \sum_{j=1}^q \beta_j h_{t-j}^{1/2} \quad (8)$$

where $\varepsilon_{t-j}^+ = \max(\varepsilon_{t-j}, 0)$, $\varepsilon_{t-j}^- = \min(\varepsilon_{t-j}, 0)$, and $\alpha_j^+, \alpha_j^-, j = 1, \dots, q$, are the corresponding parameters. Like the GJR-GARCH model, even the TGARCH model is linear in parameters. It can be generalized by assuming the switch point to be an unknown parameter, which makes the model non-linear in parameters. This type of threshold ARCH model was introduced by Li and Li [46] who also considered a threshold autoregressive conditional mean, but it has not enjoyed the same popularity as the TGARCH or the GJR-GARCH model.

Integrated and Fractionally Integrated GARCH.

In applications it often occurs, if the time series is sufficiently long, that the estimated sum of the parameters α_1 and β_1 in the GARCH(1,1) model (equation (4) with $p = q = 1$) is close to unity. Engle and Bollerslev [24], who first paid attention to this phenomenon, suggested imposing the restriction $\alpha_1 + \beta_1 = 1$ and called the ensuing model an *integrated GARCH (IGARCH) model*. The IGARCH process is not weakly stationary as $E\varepsilon_t^2$ is not finite but it is, however, strongly stationary.

The empirical fact that the estimate of the sum $\alpha_1 + \beta_1$ often lies close to unity has prompted discussion of its causes. First Diebold [18] and later Lamoureux and Lastrapes [44] suggested that this often happens if the intercept of the GARCH process does not remain constant during the estimation period. This may not be surprising as it means that the underlying GARCH process is not stationary. This has aroused interest in testing parameter constancy and finding breaks in the GARCH process; see, for example [43, 52] and [8].

The integrated GARCH model has also served as a starting point for so-called fractionally integrated GARCH (FIGARCH) models. The GARCH(1,1) equation (4) can be written in the “ARMA(1,1) form” as follows:

$$\varepsilon_t^2 = \alpha_0 + (\alpha_1 + \beta_1)\varepsilon_{t-1}^2 + v_t - \beta_1 v_{t-1} \quad (9)$$

where $\{v_t\} = \{\varepsilon_t^2 - h_t\}$ is a martingale difference sequence with respect to h_t . For the IGARCH process, equation (9) has the “ARIMA(0,1,1) form”

$$(1 - L)\varepsilon_t^2 = \alpha_0 + v_t - \beta_1 v_{t-1} \quad (10)$$

where L is the lag operator, $Lx_t = x_{t-1}$. The FIGARCH(1, d ,0) model is obtained from equation (10) simply by assuming that the difference in equation (10) is *fractional* (see **Long Range Dependence**) instead of the conventional one:

$$(1 - L)^d \varepsilon_t^2 = \alpha_0 + v_t - \beta_1 v_{t-1} \quad (11)$$

where d is the fractional order of integration. The FIGARCH equation (11) can be written as an infinite-order ARCH model by applying the definition $v_t = \varepsilon_t^2 - h_t$ to it. This yields

$$h_t = \alpha_0(1 - \beta_1)^{-1} + \lambda(L)\varepsilon_t^2 \quad (12)$$

where $\lambda(L) = \{1 - (1 - L)^d(1 - \beta_1 L)^{-1}\}\varepsilon_t^2 = \sum_{j=1}^{\infty} \lambda_j L^j \varepsilon_t^2$, and $\lambda_j \geq 0$ for all j . Expanding the fractional difference operator into an infinite sum yields the result that for long lags j ,

$$\lambda_j = \{(1 - \beta_1)\Gamma(d)^{-1}\}j^{-(1-d)} = cj^{-(1-d)}, \quad c > 0 \quad (13)$$

where $d \in (0, 1)$ and $\Gamma(d)$ is the gamma function. When $d > 0.5$, the FIGARCH model is not weakly stationary. From equation (13) it is seen that the effect of the lag ε_{t-j}^2 on the conditional variance decays hyperbolically as a function of the lag length j . A very slow decay of the autocorrelation function of $\{\varepsilon_t^2\}$ is a frequently encountered empirical fact in return series, and this is the reason for developing the FIGARCH model (see [5]). But then, it has been argued (see for example [54]) that the observed slow decay is due to breaks in the variance of the return process. The FIGARCH model thus offers a competing explanation of this empirical phenomenon.

The GARCH-in-mean Model. Since volatility is viewed as a measure of risk, GARCH models are used for assessing the risk of a portfolio. From this it follows that the GARCH type conditional variance could be useful as a representation of the time-varying risk premium in explaining excess returns, that is, returns compared to the return of a riskless asset. This extends the considerations to involve the conditional mean of the return process as well. An excess return would be a combination of the unforecastable difference ε_t between the *ex ante* and *ex post* rates of return and a function of the conditional variance of the portfolio. Thus, if y_t is the excess return at time t ,

$$y_t = \beta + g(h_t) + \varepsilon_t \quad (14)$$

where h_t is defined as a GARCH process (4) and $g(h_t)$ is a well-defined function. Engle *et al.* [26] originally defined $g(h_t) = \delta h_t^{1/2}$, $\delta > 0$, which corresponds to the assumption that changes in the conditional variance appear less than proportionally in the mean. The alternative $g(h_t) = \delta h_t$ has also appeared in the literature. Equations (4) and (14) form the GARCH-in-mean or GARCH-M model. It has been quite frequently applied in the applied econometrics and finance literature. It may be mentioned that Glosten *et al.* [32] developed the GJR-GARCH model in the framework of the GARCH-M model.

Family of Exponential GARCH Models

The standard GARCH model has some disadvantages. Parameter restrictions are required to ensure positivity of the conditional variance at every point of time. Furthermore, the model does not allow an asymmetric response to shocks. This disadvantage was overcome by the appearance of asymmetric GARCH models but this was an important reason for the introduction of the exponential GARCH (EGARCH) model by Nelson [55]. A family of EGARCH(p, q) models may be defined as in equation (2) with

$$\ln h_t = \alpha_0 + \sum_{j=1}^q g_j(z_{t-j}) + \sum_{j=1}^p \beta_j \ln h_{t-j} \quad (15)$$

When $g_j(z_{t-j}) = \alpha_j z_{t-j} + \psi_j(|z_{t-j}| - \mathbb{E}|z_{t-j}|)$, $j = 1, \dots, q$, model (15) becomes the EGARCH model of [55]. It is seen from equation (15) that no parameter restrictions are necessary to ensure

positivity of h_t . Parameters α_j , $j = 1, \dots, q$, make an asymmetric response to shocks possible.

As in the standard GARCH case, the first-order model ($p = q = 1$) is the most popular EGARCH model in practice. Nelson [55] derived existence conditions for moments of the general infinite-order exponential ARCH model. For the EGARCH model with $g_j(z_{t-j})$ defined as above, these conditions imply that if the error process $\{z_t\}$ has all moments and $\sum_{j=1}^p \beta_j^2 < 1$ in equation (15), then all moments for the EGARCH process $\{\varepsilon_t\}$ exist. For example, if $\{z_t\}$ is a sequence of independent standard normal variables, then the restrictions on β_j , $j = 1, \dots, p$, are necessary and sufficient for the existence of all moments simultaneously. For GARCH models of the previous section, the moment conditions become more and more stringent for higher and higher even moments; see [40].

There is some similarity between the EGARCH model and the autoregressive *stochastic volatility* model (see **Stochastic Volatility Models**). Introducing a sequence $\{s_t\}$ of continuous unobservable independent random variables mutually independent of $\{z_t\}$ and substituting $g_j(s_{t-j})$ for $g_j(z_{t-j})$ in equation (15) leads to another class of models. Typically, in applications, $p = q = 1$ and $g_1(s_{t-1}) = \delta s_{t-1}$ where δ is a parameter to be estimated. This is called the *autoregressive stochastic volatility model*. Strictly speaking, it is not a model of conditional heteroskedasticity, because its information set at time t also contains $\{s_{t-j}, j \geq 1\}$.

Nonparametric and Semiparametric GARCH Models

Nonparametric GARCH models have been developed to remedy some of the disadvantages of the standard GARCH model mentioned earlier. A straightforward example is the model (2) in which $h_t = h(\varepsilon_{t-1}, \dots, \varepsilon_{t-q})$ is a smooth positive-valued function estimated using nonparametric techniques. When q is large, however, this model suffers from the curse of dimensionality. This may be partly remedied by an additive function, $h_t = \sum_{j=1}^q h_j(\varepsilon_{t-j})$, where $h_j(\varepsilon_{t-j})$, $j = 1, \dots, q$, are positive-valued functions that are estimated separately. Both of these models are ARCH models. Engle and Ng [27] introduced the following semiparametric GARCH model:

$$h_t = h(\varepsilon_{t-j}) + \beta h_{t-1} \quad (16)$$

where $h(\cdot)$ is a smooth unknown function to be estimated. With $j = 1$ this functional form is more flexible than the standard GARCH(1,1) model and allows modeling possible asymmetry in returns. For more discussion of nonparametric and semiparametric ARCH and GARCH models, see [50].

Estimation of GARCH Models and Properties of Estimators

The parameters of the GARCH(p, q) model (4) and its extensions may be estimated jointly by maximum likelihood. Asymptotic theory for the estimators has been developed over the years. Weiss [70] already proved consistency and asymptotic normality for maximum likelihood estimators in the ARCH(q) case under the assumption $E\varepsilon_t^4 < \infty$, which implies $Ez_t^4 < \infty$. General results are provided by Berkes *et al.* [9] who showed the asymptotic normality of the quasi-maximum likelihood (QML) estimators of the parameters of the GARCH(p, q) model where only the moment restriction $E|z_t^2|^{2+\delta} < \infty$, $\delta > 0$, is required. Francq and Zakoian [30] proved asymptotic normality of QML estimators for yet another set of conditions, and their results included the ARMA-GARCH family of models. Straumann and Mikosch [66] derived conditions for asymptotic normality of the QML estimators for a class of GARCH models that also includes some nonlinear GARCH models. In particular, they verified these conditions for the estimators of the AGARCH model. The corresponding conditions for the GARCH-in-mean model have not been verified, although consistency of the maximum likelihood estimators has been proven; see [53].

Rather often, the parameters of GARCH models are estimated assuming a t -distribution for the errors. This choice is based on empirical observation suggesting that the residuals of the estimated GARCH models assuming normality tend to be leptokurtic. If the t -distribution is applied, its degrees-of-freedom parameter or its inverse is generally estimated as well.

The parameters of GARCH models have to be estimated numerically because the conditional variances are not observed and have to be estimated separately for each iteration, that is, conditionally on parameter estimates obtained from the previous iteration. The estimated unconditional variance is used as the starting value for $h_0, h_{-1}, \dots, h_{-(p-1)}$, whereas $\hat{\varepsilon}_0^2 = \dots = \hat{\varepsilon}_{-q+1}^2 = 0$. In practice, the most popular algorithm for estimating GARCH models

by maximum likelihood has been the so-called Berndt–Hall–Hall–Hausman (BHHH) algorithm. Its popularity is partly based on the fact that it does not require the second derivatives of the log-likelihood function. Those may be considered difficult to compute given their recursive structure. Nevertheless, Fiorentini *et al.* [29] worked out the analytical second derivatives of the log-likelihood function for the GARCH model. This makes iterative estimation of parameters by the Newton–Raphson algorithm possible.

Several econometric software packages contain a module for estimating GARCH models. Brooks *et al.* [15] studied a number of them, focusing on numerical accuracy of the estimates. Their conclusion was that the algorithms based on analytical derivatives are preferable to the other alternatives. The best performing package used both analytical first and second derivatives. The authors reported substantial differences in numerical accuracy between the packages considered.

The parameters of the EGARCH model are also estimated by maximum likelihood. Nelson [55] gives the log-likelihood function based on the assumption that the errors follow a generalized error distribution (GED) with mean zero. The normal distribution is a special case of the GED. Nelson also discusses the role of the starting values in the estimation. In his simulations, the use of other starting values rather than the unconditional mean of $\ln h_t$ very rapidly leads to values of h_t obtained by starting from $E \ln h_t$. As in the case of GARCH models, the precision of the estimates may be expected to depend heavily on whether or not analytical derivatives of the log-likelihood are used in iterative estimation.

Properties of the QML estimators of the EGARCH(1,1) model have been considered by Straumann and Mikosch [66] who verified conditions for consistency of these estimators. The authors pointed out that verifying the corresponding conditions for asymptotic normality of the QML estimators is still an open question.

Multivariate Models of Conditional Heteroskedasticity

General Multivariate GARCH Model

The univariate GARCH model has been generalized to the vector case, which makes it possible to model

and forecast not only conditional variances of asset returns but covariances between returns as well. This has relevance in portfolio management. In the most general multivariate GARCH model, the so-called VEC-GARCH model of [14], every conditional variance and covariance is a linear function of all previous conditional variances and covariances. Assume a vector of returns $\mathbf{e}_t = (\varepsilon_{1t}, \dots, \varepsilon_{mt})'$ such that $\mathbf{E}\mathbf{e}_t = \mathbf{0}$ and $\mathbf{E}(\mathbf{e}_t \mathbf{e}_t' | \mathcal{F}_{t-1}) = \mathbf{H}_t = [h_{ijt}]$ where $\mathbf{H}_t$ is positive definite almost surely. It follows that

$$\mathbf{e}_t = \mathbf{H}_t^{1/2} \mathbf{z}_t \quad (17)$$

where $\mathbf{z}_t \sim \text{iid}(\mathbf{0}, \mathbf{I}_m)$. The VEC-GARCH(p, q) model is defined as follows:

$$\begin{aligned} \text{vech}(\mathbf{H}_t) &= \boldsymbol{\omega} + \sum_{k=1}^q \mathbf{A}_k \text{vech}(\mathbf{e}_{t-k} \mathbf{e}_{t-k}') \\ &+ \sum_{k=1}^p \mathbf{B}_k \text{vech}(\mathbf{H}_{t-k}) \end{aligned} \quad (18)$$

where $\mathbf{A}_k = [\alpha_{kij}]$ and $\mathbf{B}_k = [\beta_{kij}]$ are coefficient matrices with $m(m+1)/2$ rows and columns, and $\boldsymbol{\omega}$ is an $(m(m+1)/2) \times 1$ intercept vector with positive elements.

In equation (18), the number of parameters increases rapidly with the dimension of $\mathbf{e}_t$. Besides, general conditions for positive definiteness of $\mathbf{H}_t$ do not seem to exist. A simplified version in which the coefficient matrices $\mathbf{A}_k$ and $\mathbf{B}_k$ are diagonal has sometimes been applied. For this process, it is possible to work out the conditions for $\mathbf{H}_t$ to be positive definite, at least in the first-order case. In many applications, however, this model is already too restrictive, because it excludes any interaction between the conditional variances and covariances.

Bollerslev *et al.* [14] considered estimation of the general model and concluded that under sufficient regularity conditions the maximum likelihood estimator of the parameter vector is consistent and asymptotically normal. They used the BHHH optimization algorithm for obtaining the maximum likelihood estimates. Estimation of the VEC-GARCH model is, however, computationally demanding. The number of parameters can be large. Furthermore, the matrix $\mathbf{H}_t$ has to be inverted for each t in every iteration. It is likely that numerical considerations are at least as important here as they are in the univariate case. The

use of analytical first- and second-order derivatives would thus be preferable if they are available.

Constant Conditional Correlation Multivariate GARCH

There exist multivariate GARCH models with fewer parameters than the VEC-GARCH model. The constant conditional correlation GARCH (CCC-GARCH) model by Bollerslev [11] is built on the assumption that the conditional correlations between variables remain constant over time. This assumption is more parsimonious than the VEC-GARCH one, because the conditional covariances are determined through conditional variances and these correlations. Suppose again that $\mathbf{e}_t = (\varepsilon_{1t}, \dots, \varepsilon_{mt})'$ such that $\mathbf{E}\mathbf{e}_t = \mathbf{0}$ and $\mathbf{E}(\mathbf{e}_t \mathbf{e}_t' | \mathcal{F}_{t-1}) = \mathbf{H}_t = [h_{ijt}]$ where $\mathbf{H}_t$ is positive definite almost surely. The CCC-GARCH model has the following structure:

$$\mathbf{H}_t = \mathbf{D}_t \mathbf{P} \mathbf{D}_t \quad (19)$$

where $\mathbf{D}_t = \text{diag}(h_{11t}^{1/2}, \dots, h_{mmt}^{1/2})$ and $\mathbf{P} = [\rho_{ij}]$ is the positive definite correlation matrix, so that $h_{ijt} = \rho_{ij}(h_{iit}h_{jjt})^{1/2}$ for $i, j = 1, \dots, m$. Each conditional variance is assumed to follow a standard univariate GARCH model (4). The most common choice is the first-order GARCH model: $p = q = 1$. In this case, a bivariate first-order CCC-GARCH model has 7 parameters compared to 21 in the corresponding VEC-GARCH model.

One of the attractions of the CCC-GARCH model is that the parameter estimation is not complicated. The (conditional) quasi log-likelihood function of any GARCH model with $\mathbf{e}_t | \mathcal{F}_{t-1} \sim \text{iid } \mathcal{N}(\mathbf{0}, \mathbf{H}_t)$ has the form

$$L(\boldsymbol{\theta}) = c - (1/2) \sum_{t=1}^T (\ln |\mathbf{H}_t| - \mathbf{e}_t' \mathbf{H}_t^{-1} \mathbf{e}_t) \quad (20)$$

where $\boldsymbol{\theta}$ is the parameter vector. As already mentioned, maximizing equation (20) can be computationally quite costly when the model is the VEC-GARCH model, because an $m \times m$ matrix has to be inverted T times during a single iteration. The assumption of constant conditional correlations considerably simplifies things. Following Bollerslev [11], rewrite the conditional variances as $h_{jjt} = k_j \sigma_{jt}^2$, where $k_j > 0$, $j = 1, \dots, m$. Then one may partition the covariance matrix $\mathbf{H}_t$ as follows:

$$\mathbf{H}_t = \mathbf{D}_t^* \boldsymbol{\Gamma} \mathbf{D}_t^* \quad (21)$$

where $\mathbf{D}_t^* = \text{diag}(\sigma_{1t}, \dots, \sigma_{mt})$ and $\mathbf{\Gamma} = [\gamma_{ij}] = [\rho_{ij}(k_i k_j)^{1/2}]$. Applying equation (21) to equation (20) and keeping in mind that $\mathbf{D}_t^*$ is a diagonal matrix yields

$$L(\theta) = c - (T/2) \ln |\mathbf{\Gamma}| - \sum_{t=1}^T \sum_{j=1}^m \ln \sigma_{jt} - (1/2) \sum_{t=1}^T \bar{\mathbf{e}}_t' \mathbf{\Gamma}^{-1} \bar{\mathbf{e}}_t \quad (22)$$

where $\bar{\mathbf{e}}_t = \mathbf{D}_t^{*-1} \mathbf{e}_t$. In the maximization of equation (22), only a single matrix inversion is needed for each iteration. Even here, the BHHH optimization algorithm has been recommended for maximizing the log-likelihood. The calculations can be made even simpler by concentrating the log-likelihood, but the derivatives of the original log-likelihood (22) are required for obtaining an estimate of the asymptotic covariance matrix of the estimators of the parameters. The correlations are recovered from the relationship $\rho_{ij} = \gamma_{ij}(k_i k_j)^{-1/2}$.

Results on statistical properties of the QML estimators of a stationary CCC-GARCH model are available. Under appropriate regularity conditions, Jeantheau [41] proved consistency of these estimators and Ling and McAleer [49] verified conditions for their asymptotic normality.

The Dynamic Conditional Correlation GARCH Model

The assumption of constant correlations, however, does not always hold in practice. Tse and Tsui [68] and Engle [23] have extended the CCC-GARCH model by introducing time variation in the correlation matrix, and the two models are quite similar. The dynamic conditional correlation (DCC-) GARCH model of [23] has the following GARCH(1,1) form:

$$\begin{aligned} q_{ijt} &= \rho_{ij}(z) + \alpha^*(z_{i,t-1} z_{j,t-1} - \rho_{ij}(z)) \\ &\quad + \beta^*(q_{ij,t-1} - \rho_{ij}(z)) \\ &= (1 - \alpha^* - \beta^*) \rho_{ij}(z) + \alpha^* z_{i,t-1} z_{j,t-1} \\ &\quad + \beta^* q_{ij,t-1}, \quad i \neq j \end{aligned} \quad (23)$$

where $\rho_{ij}(z)$ is the unconditional correlation between z_{it} and z_{jt} , and $\alpha^* + \beta^* < 1$. If $\mathbb{E}q_{ijt} < \infty$, it

follows that $\mathbb{E}q_{ijt} = \rho_{ij}(z)$. The intercept is defined by variance targeting. The two ‘‘GARCH parameters’’ α^* and β^* are the same for all correlations. This makes it possible to model a large number of assets at the same time. The estimated conditional correlations are obtained *ex post* by making use of the relationship

$$\rho_{ijt} = \frac{q_{ijt}}{\sqrt{q_{iit} q_{jjt}}} \quad (24)$$

When $\alpha^* + \beta^* = 1$ in (23), ρ_{ijt} is determined by exponential smoothing.

Estimation of parameters of the DCC-GARCH model can be carried out as follows. The parameters of the individual GARCH equations contained in $\mathbf{D}_t$ (see equation (19)) can be estimated equation by equation assuming that $\mathbf{P} = \mathbf{I}_m$. Conditionally upon the results, one can then estimate the correlation parameters using the estimated standardized residuals z_{it} in equation (23). For example, assuming the parameters in $\mathbf{D}_t$ are known, the remaining parameters can be estimated by direct maximization of

$$\begin{aligned} L_T(\theta_{\text{corr}}) &= c - (1/2) \sum_{t=1}^T \ln |\mathbf{P}_t| \\ &\quad - (1/2) \sum_{t=1}^T \mathbf{z}_t' \mathbf{P}_t^{-1} \mathbf{z}_t \end{aligned} \quad (25)$$

where the elements of $\mathbf{P}_t$ are defined as in equation (23). Under regularity conditions, the estimators based on this two-step method are consistent but inefficient. Engle [23] also discusses simplified ways of obtaining estimates for the correlation parameters.

The CCC-GARCH model has other extensions that are not considered here. A few of them are based on the idea that the time-varying correlation matrix is a time-varying convex combination of two or more positive definite correlation matrices; see [7, 58] and [62, 63] for details.

The BEKK-GARCH Model

The BEKK-GARCH model (BEKK stands for Baba, Engle, Kraft and Kroner) is discussed in detail in [25]. It is another parsimonious GARCH model and has the property that the conditions of positive definiteness of the conditional covariance matrix are known. The

model is defined by completing equation (17) with

$$\begin{aligned} \mathbf{H}_t = & (\mathbf{C}_0^*)' \mathbf{C}_0^* + \sum_{k=1}^K \sum_{j=1}^q (\mathbf{A}_{jk}^*)' \boldsymbol{\varepsilon}_{t-j} \boldsymbol{\varepsilon}_{t-j}' \mathbf{A}_{jk}^* \\ & + \sum_{k=1}^K \sum_{j=1}^p (\mathbf{B}_{jk}^*)' \mathbf{H}_{t-j} \mathbf{B}_{jk}^* \end{aligned} \quad (26)$$

where $\mathbf{C}_0^* = (\mathbf{c}_{01}', \dots, \mathbf{c}_{0m}')'$ is an $m \times m$ triangular matrix, and $\mathbf{A}_{jk}^* = [\alpha_{jk,il}^*]$ and $\mathbf{B}_{jk}^* = [\beta_{jk,il}^*]$ are $m \times m$ coefficient matrices. When $\mathbf{C}_0^*$ is of full rank so that $(\mathbf{C}_0^*)' \mathbf{C}_0^*$ is positive definite, it follows that $\mathbf{H}_t$ is positive almost surely if the starting values $\mathbf{H}_0, \mathbf{H}_{-1}, \dots, \mathbf{H}_{-p+1}$ are positive semidefinite matrices, and $\boldsymbol{\varepsilon}_0, \boldsymbol{\varepsilon}_{-1}, \dots, \boldsymbol{\varepsilon}_{-q+1} = \mathbf{0}$. This is the main attraction of the BEKK-GARCH model. In applications, it is typically assumed that $K = p = q = 1$.

The log-likelihood function of the BEKK model is equation (20), and its partial derivatives are defined through equation (26). Engle and Kroner [25] remark that in the GARCH case (as opposed to ARCH) calculating analytical derivatives is complicated because it requires recursive computation of certain derivatives. They therefore recommend numerical derivatives and the BHHH algorithm. Nevertheless, Luchetti [51] has worked out the analytical score for the first-order BEKK-GARCH model when $K = 1$. Given the results reported in [15] in the univariate case, it appears that making use of the analytical score in the estimation of the parameters of this model would be very useful. Conditions for the asymptotic normality of the QML estimators of the parameters of the BEKK-GARCH model can be found in [17].

Factor GARCH Models

Observable Factor GARCH Models. The BEKK-GARCH model may be used as a starting point in a search for even more parsimonious models. Assume that, for each k , the matrices $\mathbf{A}_{jk}^*$ and $\mathbf{B}_{jk}^*$ in equation (26) have rank one and the same $m \times 1$ eigenvectors, $\mathbf{g}_k$ for $\mathbf{A}_{jk}^*$ and $\mathbf{f}_k$ for $\mathbf{B}_{jk}^*$, respectively, with $\mathbf{g}_k' \mathbf{f}_i = 0$, $i \neq k$, and $\mathbf{g}_k' \mathbf{f}_k = 1$. Then equation (26) collapses into

$$\mathbf{H}_t = \boldsymbol{\Omega} + \sum_{k=1}^K \mathbf{g}_k \mathbf{g}_k' \left\{ \sum_{j=1}^q \alpha_{kj}^2 \gamma_{k,t-j}^2 + \sum_{j=1}^p \beta_{kj}^2 h_{k,t-j}^{(f)} \right\} \quad (27)$$

where $\boldsymbol{\Omega} = (\mathbf{C}_0^*)' \mathbf{C}_0^*$, $\gamma_{kt} = \mathbf{f}_k' \boldsymbol{\varepsilon}_t$ and $h_{kt}^{(f)} = \mathbf{f}_k' \mathbf{H}_t \mathbf{f}_k$. This is the K -factor GARCH model of [28]. Each factor γ_{kt} has a univariate GARCH(p, q) structure: $\gamma_{kt} | \mathcal{F}_{t-1} \sim \mathcal{D}(0, h_{kt}^{(f)})$ where $\mathcal{D}$ denotes a distribution, such that the conditional variance

$$h_{kt}^{(f)} = c_k + \sum_{j=1}^q \alpha_{kj}^2 \gamma_{k,t-j}^2 + \sum_{j=1}^p \beta_{kj}^2 h_{k,t-j}^{(f)} \quad (28)$$

where $c_k = \mathbf{f}_k' \boldsymbol{\Omega} \mathbf{f}_k$. Writing $\gamma_{kt} = z_{kt} (\mathbf{f}_k' \mathbf{H}_t \mathbf{f}_k)^{1/2}$, $k = 1, \dots, K$, where $\{z_{kt}\} \sim \text{iid}(0, 1)$ such that $\mathbf{E} z_{kt} z_{jt} = \omega_{kj}$, it follows that γ_{kt} and γ_{jt} have a constant conditional correlation ω_{kj} . The model consisting of equations (17) and (27) and characterizing $\boldsymbol{\varepsilon}_t$ is just a linear combination of the K conditional variances of the univariate common factors γ_{kt} . It is important to note that the factors γ_{kt} , $k = 1, \dots, K$, are observable and not latent variables because $\mathbf{f}_k$, $k = 1, \dots, K$, are assumed known.

This model has an economic interpretation. Theories of asset pricing suggest that the risk premium of an asset depends on its covariance with other assets as well as its own variance. The factor GARCH model represents those covariances in a parsimonious way and makes it possible to simultaneously consider a larger number of asset returns than many other vector GARCH models would allow in practice. The K factors define as many portfolios of these assets. It is then reasonable to assume that the elements of $\mathbf{f}_k$ are nonnegative and sum up to one.

The predetermined factors in this model can be correlated. There are also factor models with uncorrelated factors. The factors are obtained through a one-to-one transformation of $\boldsymbol{\varepsilon}_t$:

$$\boldsymbol{\varepsilon}_t = \mathbf{W} \mathbf{f}_t \quad (29)$$

where $\mathbf{W}$ is a nonsingular $m \times m$ matrix. Each f_{jt} in $\mathbf{f}_t = (f_{1t}, \dots, f_{mt})'$ is thus a function of the elements of $\boldsymbol{\varepsilon}_t$ and is typically assumed to follow a GARCH process. The specification of $\mathbf{W}$ varies from one model to the next. Examples include [1, 69] and [45].

The parameters of the factor GARCH model (17) and (27) can be estimated by QML with restrictions $\mathbf{g}_k' \mathbf{f}_i = 0$, $i \neq k$, and $\mathbf{g}_k' \mathbf{f}_k = 1$, but this can be numerically difficult. The fact that the common conditional variances can be viewed as generated by univariate GARCH processes suggests two-step estimation of parameters. First, c_k , α_{kj}^2 and β_{kj}^2 and the common conditional variances $h_{kt}^{(f)}$ are estimated from the K

univariate GARCH equations (28). Equation (27) is then rewritten as

$$\mathbf{H}_t = [h_{ijt}] = \left\{ \boldsymbol{\Omega} - \sum_{k=1}^K c_k \mathbf{g}_k \mathbf{g}_k' \right\} + \sum_{k=1}^K \mathbf{g}_k \mathbf{g}_k' h_{kt}^{(f)} \quad (30)$$

At the second stage, the remaining parameters are estimated making use of equation (30) and the estimates of c_k and $h_{kt}^{(f)}$. Lin [48] considers the estimation of factor GARCH models, including these two methods, the QML and the two-step one. More details and references can be found in that paper.

Unobserved Factor Models. In the factor model (27), the factors at time t , as can be seen from equation (30), are functions of observed variables $\boldsymbol{\varepsilon}_{t-j}$, $j \geq 1$. Another strand of factor GARCH models has drawn inspiration from the factor analysis and builds on genuinely unobserved factors. In a general form, one may write

$$\boldsymbol{\varepsilon}_t = \mathbf{C}\mathbf{f}_t + \boldsymbol{\eta}_t \quad (31)$$

where $\mathbf{f}_t$ is now a $k \times 1$ vector of unknown factors such that $\mathbf{E}\mathbf{f}_t = 0$ and $\text{cov}(\mathbf{f}_t | \mathcal{F}_{t-1}) = \boldsymbol{\Lambda}_t$ where $\boldsymbol{\Lambda}_t$ is a time-varying covariance matrix, often assumed diagonal, and $\mathbf{C}$ is an $m \times k$ matrix of factor loadings with rank $k \leq m$. Furthermore, for the disturbance vector, $\mathbf{E}\boldsymbol{\eta}_t = 0$ and $\text{cov}(\boldsymbol{\eta}_t | \mathcal{F}_{t-1}) = \boldsymbol{\Sigma}_\eta$, and $\mathbf{E}\{\mathbf{f}_t \boldsymbol{\eta}_t' | \mathcal{F}_{t-1}\} = \mathbf{0}$. The information set $\mathcal{F}_{t-1}$ contains the unobservable variables $\mathbf{f}_{t-j}$, $j \geq 1$, unlike the econometrician's information set $\mathcal{F}_{t-1}$ that only contains the observable variables $\boldsymbol{\varepsilon}_{t-j}$, $j \geq 1$. In [60], it is shown that there always exists a model of type (31) such that the observable factor model (27) is observationally equivalent to it.

Diebold and Nerlove [20] introduced a model of form (31), in which $k = 1$ and $\mathbf{f}_t$ has an ARCH structure. They use it to model the volatility of a set of weekly spot exchange rates. In their model,

$$\boldsymbol{\varepsilon}_t = \boldsymbol{\gamma} f_t + \boldsymbol{\eta}_t$$

$$\mathbf{E}(f_t | \mathcal{F}_{t-1}) = h_t^{(f)} = \alpha_0 + \sum_{j=1}^q \alpha_j f_{t-j}^2 \quad (32)$$

From equation (32) it follows that

$$\mathbf{H}_t = \mathbf{E}(\boldsymbol{\varepsilon}_t \boldsymbol{\varepsilon}_t' | \mathcal{F}_{t-1}) = h_t^{(f)} \boldsymbol{\gamma} \boldsymbol{\gamma}' + \boldsymbol{\Sigma}_\eta \quad (33)$$

The conditional variances and covariances are thus determined by a single factor. Diebold and Nerlove [20] estimated the parameters of (32) using the Kalman filter.

Final Remarks

The literature on GARCH models is quite voluminous. Modern econometrics texts contain accounts of conditional heteroskedasticity. A number of surveys of GARCH models exist as well. Bollerslev *et al.* [13], Diebold and Lopez [19], Palm [57], and Guégan [36] survey developments till the early 1990s; see [31] for a very recent survey. Shephard [61] considers both univariate GARCH and stochastic volatility models. Gouriéroux [34] concentrates on ARCH models, both univariate and multivariate. The survey by Bollerslev *et al.* [12] also reviews applications to financial series. The focus in [65] is on estimation in models of conditional heteroskedasticity. Theoretical results on time series models with conditional heteroskedasticity are also reviewed in [47]. Engle [22] provides a selection of the most important articles on ARCH and GARCH models up until 1993. Recent surveys of multivariate GARCH models include [6] and [64]. Several articles in [4] provide detailed descriptions of various aspects of GARCH models and their use in applications.

Volatility

Financial volatility is, loosely speaking, a measure of the variability of asset returns (*see Stochastic Volatility Models*). It has been known for a long time that volatility changes through time. Both *ex post* and *ex ante* volatility measures are in common use. The most well-known *ex post* measure is realized volatility (Rvol), while *ex ante* measures include those generated by the ARCH-type models and option-based numbers such as implied volatility (*see Implied Volatility Surface*) and the VIX. Reviews of this literature include, among others, [4, 12, 23, 36].

We focus here on high frequency *ex post* measures of volatility and models of volatility driven by Lévy processes. Throughout our discussion, we refer to a vector of price processes

$$Y_t = Y_0 + \int_0^t \mu_u du + \int_0^t \sigma_u dW_u, \quad t \geq 0 \quad (1)$$

where W_t is Brownian motion and μ_t, σ_t are spot drift and volatility. We write $\mathcal{F}_t$ as the continuous time record of the past Y_t . For simplicity of exposition, we ignore jumps in the price process.

Ex post Measures

Itô's formula (*see Itô's Formula*) implies

$$\begin{aligned} \text{Var} \left\{ \left(Y_t - Y_0 - \int_0^t \mu_u du \right) | \mathcal{F}_0 \right\} \\ = E \left\{ \int_0^t \sigma_u \sigma_u' du | \mathcal{F}_0 \right\} \\ = E \{ [Y, Y]_t | \mathcal{F}_0 \} \end{aligned} \quad (2)$$

linking together *ex ante* variance forecasts with *ex ante* forecasts of the quadratic variation $[Y, Y]$ of Y . However, we can use high-frequency data to estimate the $[Y, Y]_t$ process, which allows us to project this quantity into the future without an explicit model for the spot volatility matrix σ_t . This method of constructing forecasts of volatility through QV was developed by Andersen *et al.* [2] (*see Realized Volatility and Multipower Variation*).

There is active literature on estimating the $[Y, Y]_t$ process. Most of it deals with estimating discrete

increments of the process over specified time periods, such as a day, $IV_i = [Y, Y]_i - [Y, Y]_{i-1}$. The most familiar estimator is the realized variance (RV), for the i th day, which is

$$RV_i = \sum_{i-1 < t_j \leq i} (Y_{t_j} - Y_{t_{j-1}})(Y_{t_j} - Y_{t_{j-1}})' \quad (3)$$

where t_j are the times at which data is available—which could represent the times of trades and quotes (or a subset of such trades and quotes). In the univariate case, the square root of RV is the realized volatility. Many option contracts are directly written on Rvol and RV, but usually this is where volatility is measured over the month and daily returns are used in equation (3).

The econometric theory associated with RV uses an in-fill asymptotic analysis, imagining $t_j - t_{j-1} \downarrow 0$. This is somewhat problematic as equation (1) ignores market microstructure effects (*see Market Microstructure Effects*) which bite in the limit. However, for the moment we ignore this. Then, $RV_i \xrightarrow{P} IV_i$ by the definition of QV. The central limit theory extension of this, in the univariate case, is

$$\widehat{V}_i^{-1/2} \sqrt{n} (RV_i - IV_i) \xrightarrow{d} N(0, 1) \quad (4)$$

and was developed by Barndorff-Nielsen and Shephard [11] (who suggested a variety of $\widehat{V}_i$ quantities). See also [28, 31, 32]. Figure 1 illustrates this (together with results from another estimator discussed below), showing 95% confidence intervals using 20-min returns for General Electric, based on trades made on the stock exchange in November 2004.

Zhou [41] was the first to formally study the properties of RV-type statistics in the presence of market microstructure noise—which causes returns to be autocorrelated in time. Here, we think of noise as $U = X - Y$, where X is the observed trade or quote process and Y continues to be the underlying efficient price. Modern research has developed three methods for being robust to noise: preaveraging, [29] multiscale [40] and [39], and realized kernels [6, 7].

We focus on realized kernels, which generalize RV to

$$K(X) = \sum_{h=-H}^H k\left(\frac{h}{H+1}\right) \gamma_h, \quad \gamma_h = \sum_{j=|h|+1}^n r_j r_{j-|h|} \quad (5)$$

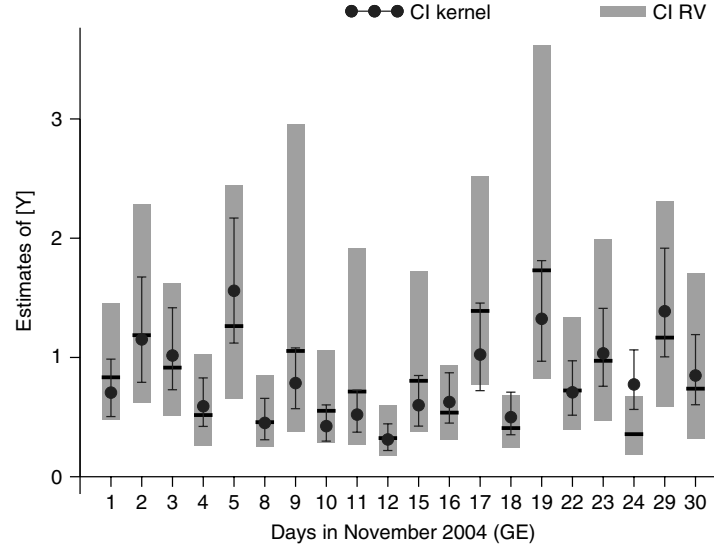

Figure 1 Daily estimates of *ex post* variability: RV and realized kernel, together with 95% confidence intervals

where $\{r_j\}$ are high-frequency data and k is a Parzen weight function:

$$k(x) = \begin{cases} 1 - 6x^2 + 6x^3, & 0 \leq x \leq 1/2 \\ 2(1 - x)^3, & 1/2 \leq x \leq 1 \\ 0, & x > 1 \end{cases} \quad (6)$$

This is like an HAC estimator, which is popular in econometrics, but there is no scaling by sample size. It is robust to (i) irregularly spaced data, (ii) endogenous noise, and (iii) autocorrelation in the noise. A key feature of realized kernels is the choice of the bandwidth H . The value that approximately minimizes the asymptotic MSE of the estimator is $H = 0.97\xi^{4/5}n^{3/5}$, $\xi^2 = \text{Var}(X - Y)/IV$. Figure 1 illustrates the use of this method, which shows the improvement from using the high-frequency data. More details on how to implement this method are given in [8]. The multivariate implementation is discussed in [7].

These high-frequency-data-based volatility measures can be combined to make volatility forecasts in a variety of ways. Andersen *et al.* [1–3] have pioneered the use of simple linear time-series methods. An alternative is to use lagged RV measures as an explanatory variable in the volatility dynamics of an ARCH model [24].

A wide variety of diffusion-based models of volatility have been proposed (*see Stochastic Volatility Models; Local Volatility Model; Heston Model*). The leading examples of these are the models proposed by Heston [25, 27, 35], while an interesting analysis of such models is found in [22, 30].

Pure Jump-based Volatility Models

There is now quite a lot of evidence that there are jumps in the volatility process [38] and that jumps play a key role in generating statistical leverage effects [9]. An article that is a distinct break from the traditional diffusion-based stochastic volatility models associated with [27] is that of Barndorff-Nielsen and Shephard [10]. In their simplest model, these authors wrote the univariate spot variance as an OU-type process (*see Ornstein–Uhlenbeck Processes*)

$$d\sigma_t^2 = -\lambda\sigma_t^2 dt + dZ_{\lambda t}, \quad \lambda > 0 \quad (7)$$

where Z is a subordinator. It may be recalled that a subordinator is a Lévy process with nonnegative increments, which means σ_t^2 has no Brownian component at all (*see Barndorff-Nielsen and Shephard (BNS) Models*). They have the feature that if $\text{Var}(Z_1) < \infty$, then $\text{Corr}(\sigma_t^2, \sigma_{t+s}^2) = \exp(-\lambda s)$.

A main advantage of this OU process is that

$$\sigma_t^2 = e^{-\lambda t} \sigma_0^2 + \int_0^t e^{-\lambda(t-s)} dZ_{\lambda s} \quad (8)$$

and

$$\begin{aligned} \int_0^t \sigma_u^2 du &= \lambda^{-1} (1 - e^{-\lambda t}) \sigma_0^2 \\ &+ \lambda^{-1} \int_0^t \{1 - e^{-\lambda(t-s)}\} dZ_{\lambda s} \end{aligned} \quad (9)$$

Hence they are easy to analyze and simulate from.

More sophisticated dynamics can be achieved by adding together independent OU processes, each with a different decay parameter λ . Such superposition processes can be extended to the case of an infinite number of components, as analyzed by Barndorff-Nielsen [5].

A different route is to generate ARMA-type dynamics. Such processes have been advocated by Brockwell [19, 20, 37].

The OU process has been extended to the multivariate case by Barndorff-Nielsen and Stelzer [13] and [34]. They set up an OU process for the positive semidefinite covariance matrix $\Sigma_t = \sigma_t \sigma_t'$ and analyzed the properties of the resulting implied multivariate return process.

These BNS models have been used extensively in applications. Derivative pricing on the basis of this type of model was first discussed by Nicolato and Venardos [33]. Subsequent research includes [14]. Benth *et al.* [15] studied the pricing of the variance and volatility swaps based on the BNS model. Minimal martingale measures for BNS models are analyzed by Benth and Meyer-Brandis [18, 26]. Benth *et al.* [16] studied the calculation of Greeks for BNS-type models.

Benth *et al.* and Delong and Klüppelberg [17, 21] have used BNS models to provide analytic solutions to the portfolio allocation problem.

These models and variants based on them have been used as the models of prices traded in energy markets, where extreme movements are quite common (see **Electricity Markets**).

Realized Volatility and Multipower Variation

Many financial markets effectively operate in continuous time with multiple transaction prices and quotes recorded each second. Although, such “ultra high-frequency” data are not useful for assessing the expected mean return of the underlying asset, it is highly informative regarding the strength of another key financial characteristic, namely, return volatility. In particular, it is feasible to estimate the realized return volatility over a fixed time period directly from high-frequency data with good precision without imposing a specific parametric structure on the return dynamics. Hence, as access to tick-by-tick data became more commonplace and the first empirical links between cumulative absolute return measures and the underlying volatility were established in the mid-1990s, the literature on extracting time-varying return variation measures from high-frequency data has grown dramatically. The initial developments focused on measures reflecting the actual squared return variation, loosely denoted realized volatility (RV), over daily and weekly frequencies. However, extended measures capturing different return moments and/or providing more robust inference regarding the continuous *versus* jump components of the return variation process are now an integral part of this literature. The potential applications to areas such as risk management, derivatives pricing, portfolio choice, market microstructure, and general asset pricing are basically unlimited. This article briefly reviews the main developments in this literature.

A general no-arbitrage setting for a continuously evolving logarithmic asset price is given by a jump-diffusive process. Formally, on an appropriate probability space, the stochastic logarithmic price process X_t is defined *via*

$$X_t = X_0 + \int_0^t b_s ds + \int_0^t \sigma_s dW_s + \sum_{0 \leq s \leq t} \Delta X_s \quad (1)$$

where the predictable drift component, b_s , signifies the instantaneous (continuously compounded) mean return, the diffusive coefficient, σ_s , reflects the strength of the diffusive volatility, W_s denotes a standard Brownian motion, and $\Delta X_s := X_s - X_{s-}$

indicates the jump size and is nonzero only if the price jumps exactly at time s . In the definition of X_t , we implicitly assume certain (weak) regularity conditions and that jumps are of finite variation; some results below extend to the case of infinite variation jumps, [29]. Equation (1) is a generic representation of the jump-diffusive stochastic volatility model that serves as a workhorse for continuous-time finance.

We are interested in inference regarding the actual volatility displayed by X over a given interval of time $[0, T]$. In the (infeasible) scenario, where we have access to a continuous record of X_t , we can directly determine the actual realization of the so-called quadratic variation (QV) of X ,

$$QV_{[0,T]} = \int_0^T \sigma_s^2 ds + \sum_{0 \leq s \leq T} |\Delta X_s|^2 \quad (2)$$

Importantly, in the continuous-record case, we may also perfectly identify the jumps in the sample path and we thus “observe” the continuous and discontinuous parts of the QV and obtain the decomposition,

$$QV_{[0,T]}^c = \int_0^T \sigma_s^2 ds \quad \text{and} \quad QV_{[0,T]}^d = \sum_{0 \leq s \leq T} |\Delta X_s|^2 \quad (3)$$

The QV is of a particular interest as it is closely related to the (variance) risk of the asset. This is most transparent in a simplified setting. For a pure diffusion, if the (stochastic) volatility process is independent of the return innovations, and ignoring the (negligible) return variation induced by innovations to the mean drift, the returns are conditionally Gaussian with variance governed by $QV_{[0,T]}^c$. If the return interval is small, such as a day, we may safely ignore the mean drift altogether and for simplicity equate it to zero. We then have the distributional result,

$$(X_T - X_0) \Big| \{\sigma_s\}_{0 \leq s \leq T} \sim N\left(0, \int_0^T \sigma_s^2 ds\right) \quad (4)$$

Notice that the Gaussian distributional result is conditional on the realization of the so-called integrated variance which *a priori* is stochastic. In other words, the returns follow a Gaussian mixture distribution with the realization of the (diffusive) QV

governing the actual return variation. If this integrated variance process is persistent, that is, displays pronounced positive serial correlation, then the return distribution is symmetric, but displays both unconditional and conditional leptokurtosis along with volatility clustering. The main features, which may modify this characterization and induce both asymmetries and more extreme outliers in the conditional return distribution are correlation between the return innovations and the volatility, the so-called leverage effect, and the presence of jumps. Nonetheless, the interpretation of $QV_{[0,T]}$ as the relevant return variation measure remains intact. Moreover, the multivariate version of equation (4) applies as stated in [7].

In practice, we do not observe financial series continuously but rather obtain transaction price and quote data referring to specific points in time. Hence, the challenge is to design estimators from the discrete observations of X that can estimate continuous-time quantities like the QV and its decomposition into continuous and jump components. A closely related issue is the development of tests for the presence of jumps in the (partially) observed path of X . Suppose, we observe X at $0, \dots, i\Delta_n, \dots, [T/\Delta_n]\Delta_n$, where Δ_n is a small positive sampling interval and $[y]$ denotes the integer part of y . Since the time interval, T , is fixed, we cannot exploit standard “large (sample length) T ” asymptotics for developing estimation and testing procedures but instead appeal to continuous-record asymptotics, that is, $\Delta_n \rightarrow 0$. For example, we may think of $[0, T]$ as one trading day and assume that we observe the price process every 10 min, 5 min, 1 min, and so on. The exposition is split in three parts. We first define RV as a feasible estimator of QV and discuss its relation to the underlying return distribution. Next, the notion of multipower variation is introduced and we outline its use for robust inference regarding critical aspects of the quadratic return variation. In the following section, we discuss the application of realized multipower variation in formal testing for the presence of jumps. Finally, we briefly touch on procedures designed to mitigate the impact of market microstructure noise, which potentially allow for more efficient inference, as well as some multivariate generalizations of the results discussed in this article.

Realized Volatility

Realized volatility, also interchangeably referred to as *realized quadratic variation*, is defined as

$$RV_T = \sum_{i=1}^{[T/\Delta_n]} |\Delta_i^n X|^2 \quad (5)$$

where $\Delta_i^n X := X_{i\Delta_n} - X_{(i-1)\Delta_n}$. Some authors label RV_T the realized variance, and refer to its square root as the Realized volatility. However, in this article, we follow the early literature and term RV_T Realized volatility. RV_T is simply a cumulative sum of squared high-frequency observations. Its usefulness stems from the fact that it consistently estimates the (unobservable) QV as $\Delta_n \rightarrow 0$, that is,

$$RV_T \xrightarrow{\mathbb{P}} QV_T \quad (6)$$

A few comments are in order. First, the estimator is model-free and applies very broadly independent of parametric model assumptions. Moreover, it remains valid in the multivariate case as well. Second, the measure estimates the return variation over an interval and not the underlying spot volatility at any given point. In fact, inference regarding spot volatility is problematic without restrictive assumptions owing to the lack of a continuous record of price observations and the impact of microstructure frictions at ultra high frequencies. Third, RV_T resembles a rolling sample variance estimator. This statistic, labeled “historical volatility” has precedents in the literature. Fourth, Merton [36] notes that, in theory, high-frequency data can provide perfect inference whenever volatility is locally constant. Direct linkage of an empirical RV measure based on intraday returns to an underlying (stochastic) quadratic return variation appears first in [3]. Fifth, one trading day is the natural measurement period owing to the pronounced intraday volatility patterns and significant news announcement effects. These features render interpretation of realized return variation over intraday periods much more complex, [4]. Finally, it is important to recognize that RV_T provides an *ex post* estimate of the return variation, which is conceptually distinct from the *ex ante* conditional return variance.

In order to assess the accuracy with which RV_T measures QV_T , a central limit theorem (CLT)—characterizing its behavior as the sampling frequency

increases—is useful. In the simplest case without jumps it follows from [14, 16, 17] that

$$\frac{1}{\sqrt{\Delta_n}} (RV_T - QV_T) \xrightarrow{\mathcal{L}-s} \epsilon \times \sqrt{2 \int_0^T \sigma_s^4 ds} \quad (7)$$

where $\xrightarrow{\mathcal{L}-s}$ means stable convergence in law and ϵ is a standard normal variable, defined on an extension of the original probability space. Stable convergence in law strengthens the usual convergence in law by guaranteeing that the convergence in equation (7) is joint with any random variable defined on the original probability space. This property is critical for feasible asymptotic inference as well as in the application of the delta method. We further note that for two nonoverlapping intervals, the measurement errors for the QV are serially uncorrelated. Evidently, the precision of RV_T can be gauged formally only if we can obtain a measure of the so-called integrated quarticity, $IQ_T = \int_0^T \sigma_s^4 ds$, from a given set of discrete price observations. This is, in fact, feasible through the general realized multipower variation statistics introduced below. Finally, we note that bootstrapping may improve finite sample inference, [26].

The result in equation (7) can be extended to the case when X contains jumps, [29]. The realized variation then provides a consistent estimate of the overall QV. If we want to further decompose it into the continuous and jump parts, we need to exploit results pertaining to the theory for general multipower variation statistics.

Multipower Variation

The initial example of a multipower variation process is the so-called bipower variation (BV) proposed by Barndorff-Nielsen and Shephard [18, 19] and defined as

$$BV_T = \frac{\pi}{2} \sum_{i=2}^{[T/\Delta_n]} |\Delta_{i-1}^n X| |\Delta_i^n X| \quad (8)$$

The above papers prove that, even in the presence of a jump process,

$$BV_T \xrightarrow{\mathbb{P}} QV_T^c \quad (9)$$

Hence, it provides a consistent estimator for the integrated variance and we may thus further consistently estimate the jump contribution to QV *via* the difference between RV_T and BV_T . However, we note that the associated CLT for BV_T in the continuous case will not hold when jumps are present.

More generally, we may define realized multipower variation by raising m successive absolute price increments to arbitrary powers, indexed by the vector $\mathbf{p} = (p_1, \dots, p_m)$, where $p_j \geq 0$, $j = 1, \dots, m$

$$V(X; \mathbf{p}; \Delta_n)_T = (\mu_{p_1} \dots \mu_{p_m})^{-1} \times \sum_{i=m}^{[T/\Delta_n]} |\Delta_{i-m+1}^n X|^{p_m} \dots |\Delta_i^n X|^{p_1} \quad (10)$$

for μ_a denoting the a th absolute moment of a standard normal. By appropriate scaling of the realized multipower variation, *in the absence of jumps*, we obtain the corresponding convergence result

$$\Delta_n^{1-p/2} V(X; \mathbf{p}; \Delta_n)_T \xrightarrow{\mathbb{P}} \int_0^T \sigma_s^p ds \quad (11)$$

where $p = p_1 + \dots + p_m$. In analogy to the bipower variation case, this result is robust to the presence of jumps provided $\max\{p_i\}_{i=1, \dots, m} < 2$. Further generalizations and asymptotic properties are explored in [14] for X continuous. Some of these properties are extended to the case when X contains jumps in [21].

A prominent special case of multipower variation arises when $\mathbf{p}$ is a scalar. Then $V(X; p; \Delta_n)_T$ is labeled realized power variation of order p . Obviously, $V(X; 2; \Delta_n)_T$ coincides with the RV estimator. In addition, a natural estimator of integrated quarticity under the null hypothesis of no jumps may be based on the realized fourth power variation, $V(X; 4; \Delta_n)_T$. While this statistic is inconsistent under the jump alternative, many realized multipower variation statistics are consistent in the presence of jumps, including the so-called realized tripower variation with $\mathbf{p} = (4/3, 4/3, 4/3)$ and the realized quadpower variation with $\mathbf{p} = (1, 1, 1, 1)$.

An alternative way of estimating the continuous part of the QV is to use the truncated squared power variation proposed by Mancini [33, 34] and also

analyzed by Jacod [29]. It is formally defined as

$$\tilde{V}(X, 2, \Delta_n)_T = \sum_{i=1}^{\lfloor T/\Delta_n \rfloor} |\Delta_i^n X|^2 1_{\{|\Delta_i^n X| \leq \alpha(\Delta_n)^\gamma\}} \quad (12)$$

for arbitrary $\alpha > 0$ and $\gamma \in (0, 1/2)$. The intuition is simple—we discard increments higher than a given threshold in the summation of the squared returns—thus effectively discarding the impact of jumps.

Given their consistency for QV_T and QV_T^c and the absence of serial correlation in the associated measurement errors, RV_T and BV_T serve as a natural basis for measuring and forecasting return volatility. The literature is too extensive for a thorough review and so we only provide an account of a few established findings. First, Andersen *et al.* [7], demonstrate that reduced-form time-series models for a realized volatility within the ARFIMA class generate forecasts which dominate traditional stochastic volatility and GARCH models estimated from daily return data. The long memory dependence incorporated in the ARFIMA setting is invariably highly significant and an important factor in forecast performance. Another key feature in the superior forecast performance is the ability of RV_T to adapt quickly to shifts in the underlying level of volatility. This allows forecasts to be conditioned on a more accurate assessment of the current volatility state compared to models based on daily returns. Second, Andersen *et al.* [5] find that forecast performance may be boosted further through a decomposition of RV_T into the continuous and jump parts. The diffusive volatility is the main source of long-range dependence, so separating out the jumps allows for a more refined measure of the relevant volatility state and improves forecast precision correspondingly. An alternative approach exploiting a mix of different realized power variation statistics for forecasting is the so-called MIDAS regressions proposed by Ghysels *et al.* [25]. Third, Andersen *et al.* [10] provide an analytic framework for gauging the performance of reduced form a realized volatility forecasts across a broad class of popular diffusive stochastic volatility specifications, finding that the loss of predictive ability is minor relative to using (infeasible) forecasts based on the true underlying model. The usefulness of reduced form a realized volatility and (in the multivariate extension) covariation forecast models from practical perspectives is

documented, for example, in [24] and [13] for portfolio allocation, in [8] for dynamic estimation of systematic (beta) market risk, in [2] for specification testing of term structure models, and in [12] for option pricing and associated trading strategies.

Realized multipower variation also facilitates estimating general parametric continuous-time models, which are challenging because of the latency of the stochastic volatility and the presence of price jumps. Barndorff-Nielsen and Shephard [16, 20] consider estimation by computing second-order moments of realized volatility. Meddahi [35] provides moments of realized volatility across a broad class of models. Closed-form expressions for moments of general realized multipower variation statistics (e.g., bipower variation), however, are typically not known, even when the moments of their continuous-time counterparts can be computed. Bollerslev and Zhou [22] estimate affine jump-diffusion models by treating the realized volatility as the unobservable quadratic variation in a method-of-moments procedure. They show *via* simulations that the impact of the measurement error on the parameter estimates is small. Corradi and Distaso [23] provide formal justification for the estimator of [22]. They consider joint asymptotics, both long time span and continuous record, and show that (in the general case) when the intraperiod sampling frequency increases faster than sample length, the measurement error of realized volatility (and in some cases bipower variation) is asymptotically negligible. Todorov [38] further generalizes these results. He proves the uniform integrability of realized multipower variation statistics under general specifications for the price jump process and demonstrates that the realized multipower variation can be used effectively in making semiparametric inference about general classes of continuous-time models containing jumps.

Jump Testing

Another important application of realized multipower variation is to determine whether, *on a given path*, the process X contains jumps or not. This may again be accomplished in entirely model-independent fashion, that is, without imposing additional structure on X besides specification (1). Barndorff-Nielsen and Shephard [18, 19] propose testing for jumps by determining whether $QV_{[0,T]}^d$ is statistically different from zero. For this purpose, they derive the joint

asymptotic distribution of RV and BV conditional on the path of X not containing jumps.

Huang and Tauchen [28] discuss various transformations of these tests which often lead to significant improvements in finite sample test performance. They also document that these procedures generally provide reliable tests. Alternative tests for the *null hypothesis of no jumps* can be derived by replacing the bipower variation with other realized multipower variation estimates of QV_T^c or with the truncated squared power variation (see also [31] for an alternative but related jump test).

Recently, Ait-Sahalia and Jacod [1] proposed an attractive alternative to these tests. They constructed a test statistic as a ratio of power variation of order four computed over two different frequencies

$$\Phi_n^{(j)} = \frac{V(X; 4; k\Delta_n)_T}{V(X; 4; \Delta_n)_T} \quad (13)$$

where $k \geq 2$ is an integer (typically 2 or 3). This test statistic behaves very differently depending on whether X contains jumps on the (partially) observed path or not, since,

$$\Phi_n^{(j)} \xrightarrow{\mathbb{P}} \begin{cases} 1 & \text{if } X \text{ contains jumps} \\ k & \text{if } X \text{ does not contain jumps} \end{cases} \quad (14)$$

Ait-Sahalia and Jacod [1] derive the CLT for $\Phi_n^{(j)}$ both when the given path of X contains jumps and when it does not. This allows for tests of both the null of no jumps (like above) and the null of jumps.

Finally, Lee and Mykland [32] pursue a different strategy as they test for jumps at each single high-frequency observation. The motivation is that, under the null hypothesis of no jumps, the high-frequency increments, standardized by the estimated local volatility, are asymptotically normally distributed. It has the convenient feature that the exact timing of significant jumps within the trading period is identified. Andersen *et al.* [9] explore a similar strategy determining the exact location of, potentially multiple, jumps from uniform test statistics across all high-frequency returns over each trading day.

Some Important Extensions

An important feature ignored in our exposition is the impact of so-called market microstructure noise.

This refers to the patterns induced in high-frequency returns owing to features such as a discrete price grid, the absence of continuous trading, and the presence of a bid–ask spread. Hence, the observed price may be seen as a noisy indicator of an underlying ideal price contaminated by a (small) noise process. This noise component induces a bias in the empirical RV measures which tends to grow with increasing sampling frequency. As such, when a realized volatility is computed from ultra high-frequency returns, it is critical to adjust for the impact of microstructure noise. Andersen *et al.* [6] suggest gauging the highest sampling frequency at which the systematic bias induced by the noise is negligible, *via* a so-called volatility signature plot, and use that frequency for the realized volatility computation. However, it is potentially more efficient to sample more frequently and adjust for the noise component. This approach is pursued in a number of papers in the recent years; see, for example, [11, 15, 27, 39, 40]. While the asymptotic theory has developed for the case of a pure diffusive price process, the properties of the various procedures in the presence of jumps remain largely unknown. Recently, Podolskij and Vetter [37] propose to modify the bipower variation in a way which is robust both to the microstructure noise and price jumps (of finite activity).

In addition, our exposition has focused on the univariate case. If X is continuous, the multivariate extension is conceptually straightforward and has been done in [14, 17] (although the practical application can be challenging). If X contains jumps, matters are much more complicated, as realized multipower variation can behave very differently depending on whether the jumps in individual series arrive jointly or not. This is exploited by Jacod and Todorov [30], who propose tests for both whether the jumps in the individual components arrive together or not without any restriction on the possible jump dependence.

In summary, the realized volatility and related realized multipower variation literature is vibrant. Given the large efficiency gains obtained from volatility measurements exploiting high-frequency data relative to daily data and the increasing availability of tick-by-tick data, both the theoretical and the empirical research within this area will surely continue to grow in the future.

Jump Processes

Processes with Jumps in General

Although, historically, models in mathematical finance were based on Brownian motion and thus are models with continuous price paths, jump processes now play a key role across all areas of finance (see, e.g., [5]). One reason for this move into a new class of processes is that because of their distributional properties, diffusions in many cases cannot provide a realistic picture of empirically observed facts. Another reason is the enormous progress made in understanding and handling jump processes due to the development of semimartingale theory on one side and of computational power on the other side.

The simplest jump process is a process with just one jump. Let T be a random time—actually a stopping time with respect to an information structure given by a filtration $(\mathcal{F}_t)_{t \geq 0}$ —then

$$X_t = \mathbb{1}_{\{T \leq t\}} \quad (t \geq 0) \quad (1)$$

has the value 0 until a certain event occurs and then 1. Although this process looks simple, it is important in modeling credit risk, namely as the process that describes the time of default of a company. The next step leads to processes that have integer values with positive jumps of size 1 only, the so-called *counting processes* $(X_t)_{t \geq 0}$. X_t describes the number of events that have occurred between time 0 and t . This could be the number of defaults in a large credit portfolio or the number of claims customers report to an insurance company. The standard case is a *Poisson process* $(N_t)_{t \geq 0}$, where the distribution of X_t is given by a Poisson distribution with parameter λt . Equivalently, one can describe this process by requiring that the waiting times between successive jumps are independent, exponentially distributed random variables with parameter λ .

The natural extension is a *compound Poisson process* $(X_t)_{t \geq 0}$, that is, a process with stationary independent increments where the jump size is no longer 1, but given by a probability law μ . Let $(Y_k)_{k \geq 1}$ be a sequence of independent random variables with distribution $\mathcal{L}(Y_k) = \mu$ for all $k \geq 1$. Denote by $(N_t)_{t \geq 0}$ a standard Poisson process with parameter $\lambda > 0$ as described above, which is independent of $(Y_k)_{k \geq 1}$.

Then we can represent $(X_t)_{t \geq 0}$ in the following form:

$$X_t = \sum_{k=1}^{N_t} Y_k \quad (2)$$

A typical application of compound Poisson processes is to model the cumulative claim size up to time t in a portfolio of insurance contracts where the individual claim size is distributed according to μ . For the sake of analytical tractability, it is often useful to *compensate* this process, that is, to subtract the average claim size $E[X_t]$. Assuming that μ has a finite expectation and using stationarity and independence, we conclude $E[X_t] = tE[X_1]$ and therefore get the following representation:

$$X_t = tE[X_1] + (X_t - E[X_t]) \quad (3)$$

The compensated process $(X_t - E[X_t])_{t \geq 0}$ is a martingale and, therefore, equation (3) is a decomposition of the process in a linear drift $E[X_1] \cdot t$ and a martingale. Representation (3) motivates the definition of a general *semimartingale* as a process that is adapted to a filtration $(\mathcal{F}_t)_{t \geq 0}$, has paths that are right-continuous and have left limits (càdlàg paths), and allows a decomposition

$$X_t = X_0 + V_t + M_t \quad (t \geq 0) \quad (4)$$

where $V = (V_t)_{t \geq 0}$ is an adapted càdlàg process of finite variation and $M = (M_t)_{t \geq 0}$ is a local martingale. There exist processes that are not semimartingales. An important class of examples is fractional Brownian motions with the exception of usual Brownian motion, which is a semimartingale. We do not go beyond semimartingales in this discussion mainly because for semimartingales there is a well-developed theory of stochastic integration, a fact which is crucial for modeling in finance.

In general, the representation (4) is not unique. It becomes unique with a *predictable* process V if we consider *special semimartingales*. A semimartingale can be made special by taking the big jumps away, for example, jumps with absolute jump size larger than 1. This follows from the well-known fact that a semimartingale with bounded jumps is special [11, I.4.24]. Denote by $\Delta X_t = X_t - X_{t-}$ the jump at time t if there is any. Then

$$X_t - \sum_{s \leq t} \Delta X_s \mathbb{1}_{\{|\Delta X_s| > 1\}} \quad (5)$$

has bounded jumps. Further, let us note that any local martingale M (with $M_0 = 0$) admits a unique (orthogonal) decomposition into a local martingale with continuous paths M^c and a purely discontinuous, local martingale M^d ([11, I.4.18]). Assuming $X_0 = 0$, we got the following unique representation for semimartingales:

$$X_t = V_t + M^c + M^d + \sum_{s \leq t} \Delta X_s \mathbb{1}_{\{|\Delta X_s| > 1\}} \quad (6)$$

To analyze M^d in more detail, we introduce the *random measure of jumps*

$$\mu^X(\omega; dt, dx) = \sum_{s > 0} \mathbb{1}_{\{\Delta X_s(\omega) \neq 0\}} \varepsilon_{(s, \Delta X_s(\omega))}(dt, dx) \quad (7)$$

where ε_a denotes as usual the unit mass in a . Thus, μ^X is a random measure which, for fixed ω , places a point mass of size 1 on each pair $(s, \Delta X_s(\omega)) \in \mathbb{R}_+ \times \mathbb{R}$ whenever for this ω the process jumps by $\Delta X_s(\omega)$ at time s . Expressed differently for any Borel subset $B \subset \mathbb{R}$, $\mu^X(\omega; [0, t] \times B)$ counts the number of jumps with size in B which can be observed along the path $(X_s(\omega))_{0 \leq s \leq t}$. With this notation, equation (5) can be written as

$$X_t - \int_0^t \int_{\mathbb{R}} x \mathbb{1}_{\{|x| > 1\}} \mu^X(ds, dx) \quad (8)$$

The purely discontinuous local martingale M^d , that is, the process of *compensated jumps* of absolute size less than 1, has then the following form:

$$M_t^d = \int_0^t \int_{\mathbb{R}} x \mathbb{1}_{\{|x| \leq 1\}} (\mu^X - \nu^X)(ds, dx) \quad (9)$$

where ν^X is another random measure, the (*pre-*dictable) *compensator* of μ^X . Whereas μ^X counts the exact number of jumps, ν^X roughly stands for the expected, that is, the average number of jumps. The integral with respect to $\mu^X - \nu^X$ in equation (9), in general, cannot be separated in an integral with respect to μ^X and another one with respect to ν^X . This is because the sum of the small jumps

$$\sum_{s \leq t} \Delta X_s \mathbb{1}_{\{|\Delta X_s| \leq 1\}} = \int_0^t \int_{\mathbb{R}} x \mathbb{1}_{\{|x| \leq 1\}} \mu^X(ds, dx) \quad (10)$$

does not converge, in general.

Lévy Processes

For many applications, it is sufficient to reduce generality and to consider the subclass of *Lévy processes*, that is, processes with stationary and independent increments. The components in equations (6) and (9) are then

$$\begin{aligned} V_t &= bt \quad (t \geq 0) \\ M_t^c &= \sqrt{c} W_t \quad (t \geq 0) \\ \nu^X([0, t] \times B) &= tK(B) \end{aligned} \quad (11)$$

where b and c are real numbers, $c \geq 0$, $(W_t)_{t \geq 0}$ is a standard Brownian motion, and K , the *Lévy measure*, is a (possibly infinite) measure on the real line that satisfies $\int (1 \wedge x^2) K(dx) < \infty$. The law of X is completely determined by the *triplet of local characteristics* (b, c, K) since these are the parameters that appear in the classical Lévy–Khinchine formula. This formula expresses the *characteristic function* $\varphi_{X_t}(u) = E[\exp(iuX_t)]$ in the form

$$\varphi_{X_t}(u) = \exp(t\psi(u)) \quad (12)$$

with the characteristic exponent

$$\begin{aligned} \psi(u) &= iub - \frac{1}{2}u^2c \\ &+ \int (\mathrm{e}^{iux} - 1 - iux \mathbb{1}_{\{|x| \leq 1\}}) K(dx) \end{aligned} \quad (13)$$

The *truncation function* $h(x) = x \mathbb{1}_{\{|x| \leq 1\}}$ could be replaced by other versions of truncation functions, for example, smooth functions that are identical to the identity in a neighborhood of the origin and go to 0 outside this neighborhood. Changing h affects the drift parameter b , but not c or K . All the information on the jump behavior of the process $(X_t)_{t \geq 0}$ is contained in K . The frequency of large jumps, expressed by the weight K puts on the tails, determines finiteness of the moments of the process as the following result states (for proofs of the propositions see [15]).

Proposition 1 *Let $X = (X_t)_{t \geq 0}$ be a Lévy process with Lévy measure K . Then $E[|X_t|^p]$ is finite for any $p \in \mathbb{R}_+$ if and only if $\int_{\{|x| > 1\}} |x|^p K(dx) < \infty$.*

We note that if X_1 and consequently any X_t has finite expectation, then one does not have to

truncate in equation (13), that is, $h(x) = x \mathbf{1}_{\{|x| \leq 1\}}$ can be replaced by $h(x) = x$.

The sum of the big jumps which is subtracted in equation (5) is finite since there are only finitely many of them from 0 to t for every path. The *fine structure* of the paths is determined by the frequency of the small jumps. A process is said to have *finite activity* if almost all paths have only a finite number of jumps along finite time intervals. The simplest examples are Poisson and compound Poisson processes. A process is said to have *infinite activity* if almost all paths have infinitely many jumps along any time interval of finite length.

Proposition 2 *Let $X = (X_t)_{t \geq 0}$ be a Lévy process with Lévy measure K . Then X has finite activity if $K(R) < \infty$ and has infinite activity if $K(R) = \infty$.*

Since a Lévy measure has *a priori* finite mass in the tails, that is, $\int_{\{|x| > 1\}} K(dx) < \infty$, the finiteness of $K(R)$ means finiteness of $\int_{\{|x| \leq 1\}} K(dx)$. Consequently, having a finite or an infinite number of jumps along finite time intervals is determined by the mass of K around the origin. From the distribution of mass around the origin, one can also see if the sum of (infinitely many) small jumps converges or not. First, let us recall that a standard Brownian motion has paths of infinite variation. Therefore, a Lévy process has *infinite variation* as soon as it has a continuous martingale component, that is, $c > 0$ in equation (11), but infinite variation can also come from the jumps.

Proposition 3 *Let $X = (X_t)_{t \geq 0}$ be a Lévy process with triplet (b, c, K) . Then almost all paths of X have finite variation if $c = 0$ and $\int_{\{|x| \leq 1\}} |x| K(dx) < \infty$. If this integral is infinite or $c > 0$, then almost all paths of X have infinite variation.*

Figure 1 shows a simulated path of a purely discontinuous, infinite activity process with finite variation, whereas Figure 2 shows a corresponding path with infinite variation.

Important Examples

Now we discuss some of the standard examples. The Poisson process with intensity parameter λ that we considered at the beginning has a finite number of jumps in any finite time interval and is constant between successive jumps. In terms of equation (11),

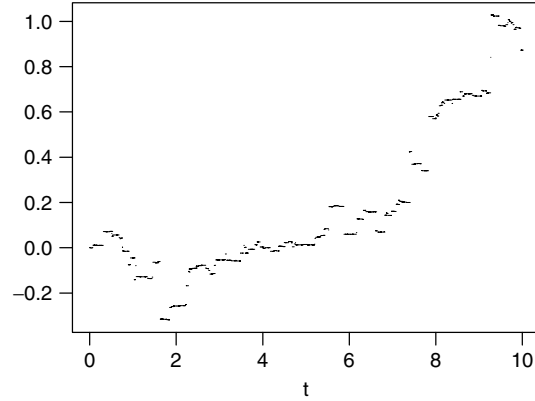

Figure 1 Simulation of a purely discontinuous Lévy process with infinite activity and finite variation

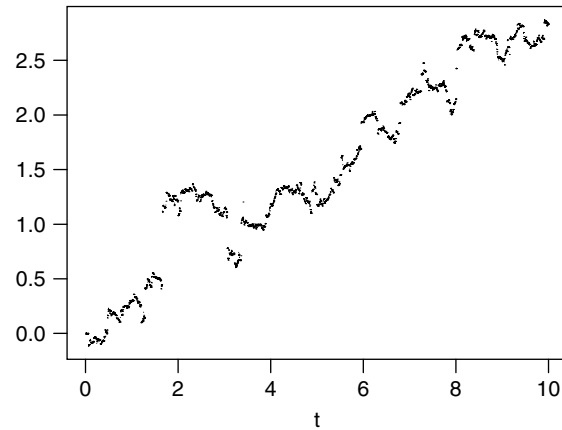

Figure 2 Simulation of a purely discontinuous Lévy process with infinite activity and infinite variation

it is characterized by $b = E[X_1] = \lambda$, $c = 0$, and $K = \lambda \varepsilon_1$. For the compound Poisson process (2), the unit mass ε_1 in K is replaced by a probability measure μ , the law of Y_1 , that is, $K = \lambda \mu$. For the drift parameter b , one gets $\lambda E[Y_1]$. One gets a *Lévy jump diffusion* by adding a general drift term bt and a scaled Brownian motion to equation (2),

$$X_t = bt + \sqrt{c}W_t + \sum_{k=1}^{N_t} Y_k \quad (14)$$

This is the model introduced by Merton [14] to describe asset returns. Merton chose normally distributed variables Y_k . In an article, Kou [12] used

double-exponentially distributed jump sizes Y_k . If one replaces in equation (14) the Brownian motion with drift by a general diffusion process one gets a *jump diffusion*. The key property of jump diffusions is that one adds only a finite number of jumps in any finite time interval to a process with continuous paths. In other words, the jump times can be given by successive stopping times $T_1 < T_2 < T_3 < \dots$. We also note that the distribution of X_t is not known for diffusions, in general. The same holds for jump diffusions. This reduces their applicability in mathematical finance. A key advantage of the pure jump Lévy processes that we discuss now is that they are distributionally very flexible and the distributions are known explicitly.

Generalized hyperbolic (GH) Lévy motions $(X_t)_{t \geq 0}$ (see *Generalized hyperbolic models* in this encyclopedia or in [6, 9]) represent a very large class of Lévy processes which are generated by GH distributions [1], that is, the distribution of X_1 , $\mathcal{L}(X_1)$, is GH. Using equation (12) all other distributions $\mathcal{L}(X_t)$ are determined. GH distributions have an explicit Lebesgue density as has the corresponding Lévy measure. GH distributions can be represented as normal mean–variance mixtures, where the mixing distribution is a generalized inverse Gaussian (GIG) distribution. Moments of any order exist. Since $c = 0$ in equation (13) GH Lévy motions have purely discontinuous paths. They are infinite activity processes. Important subclasses are hyperbolic Lévy motions ([7]) and normal inverse Gaussian (NIG) Lévy motions ([2]). Many well-known distributions can be obtained as limiting cases of GH distributions, which generate the corresponding processes [10]. Among those are the variance gamma distributions (see [13]), scaled and shifted Cauchy distributions, shifted Student- t distributions, GIG distributions, and the gamma, as well as the normal distributions.

The CGMY process introduced in [4] is another purely discontinuous Lévy process, which can be defined by the Lévy density of $\mathcal{L}(X_1)$:

$$g_{\text{CGMY}}(x) = \begin{cases} C \frac{\exp(-G|x|)}{|x|^{1+Y}} & x < 0 \\ C \frac{\exp(-Mx)}{x^{1+Y}} & x > 0 \end{cases} \quad (15)$$

where $Y \in (-\infty, 2)$. The process has infinite activity iff $Y \in [0, 2)$ and it has infinite variation iff $Y \in [1, 2)$. For $Y = 0$, it reduces to the variance gamma process.

A very classical class is given by α -stable Lévy processes where $0 < \alpha \leq 2$. For $\alpha = 2$ one gets Brownian motion, whereas for $\alpha < 2$ one gets purely discontinuous processes. Only for three special cases explicit densities are known: the Gaussian, the Cauchy, and the Lévy distribution.

A tractable extension of Lévy processes are time-inhomogeneous, Lévy processes that is, processes with independent increments and absolutely continuous characteristics, called *PIIAC* in [11]. For any fixed t , the triplet of $\mathcal{L}(X_t)$ for these processes is given in the form $b = \int_0^t b_s ds$, $c = \int_0^t c_s ds$, and $K(dx) = \int_0^t K_s(dx) ds$. This class of processes has been used extensively in the context of interest rate models (see e.g., [8]).

Jump processes with paths that are rather different from those discussed so far were introduced by Barndorff-Nielsen and Shephard [3] in the context of stochastic volatility models. Let $(Z_t)_{t \geq 0}$ be a *subordinator*, that is, a Lévy process, starting at 0 with increasing paths and consequently without a Gaussian component. The volatility process $(\sigma_t^2)_{t \geq 0}$ is modeled by an Ornstein–Uhlenbeck-type stochastic differential equation

$$d\sigma_t^2 = -\lambda\sigma_t^2 dt + dZ_{\lambda t} \quad (16)$$

for some $\lambda > 0$. The solution $(\sigma_t^2)_{t \geq 0}$ moves up entirely by jumps and then tails off exponentially. σ_t is fed into a Brownian semimartingale that then represents the price process.

Autoregressive Moving Average (ARMA) Processes

Autoregressive moving average (ARMA) processes $\{Y_t, t = 0, \pm 1, \dots\}$ have played a key role as stationary models for time series observed at regularly spaced times. They constitute a very convenient parametric family, capable of exhibiting a broad range of dependence structures and marginal distributions. Well-established prediction, model-selection, and estimation techniques are also available and the asymptotic properties of the customary estimators are well understood. Continuous-time ARMA (denoted CARMA) processes play an analogous role in continuous time. Although continuous-time data is very rarely available, it is often the case that observations of a time series at discrete times can be fruitfully regarded as sampled values of an underlying continuous-time process. The continuous-time framework is very convenient for the modeling of high-frequency data and for dealing with irregularly spaced discrete-time data. Many of the problems of mathematical finance are formulated most conveniently in a continuous time setting, and in constructing more complex continuous-time models for financial data, CARMA processes also play a role. Although ARMA and CARMA processes with infinite second moments can be defined (see [3] and [7]) we restrict our attention here to second-order processes, for which these moments are finite.

ARMA Processes

The process $\{Y_n, n = 0, \pm 1, \dots\}$ is said to be an ARMA(p, q) process with (real-valued) parameters $\{\phi_1, \dots, \phi_p; \theta_1, \dots, \theta_q; \sigma\}$ if it is a stationary solution of the equations

$$Y_n - \phi_1 Y_{n-1} - \dots - \phi_p Y_{n-p} = \sigma(Z_n + \theta_1 Z_{n-1} + \dots + \theta_q Z_{n-q}) \quad (1)$$

where $\sigma > 0$, $\phi_p \neq 0$, $\theta_q \neq 0$, $\{Z_n\}$ is standard white noise, i.e., a sequence of uncorrelated random variables with mean 0 and variance 1 (written $\{Z_n\} \sim \text{WN}(0, 1)$) and the polynomials $\phi(z) := (1 - \phi_1 z -$

$\dots - \phi_p z^p)$ and $\theta(z) := (1 + \theta_1 z + \dots + \theta_q z^q)$ have no common zeros. Stationarity here means EY_t is independent of t and $E(Y_{t+h}Y_t)$ is independent of t for all h . It can be shown (see [5]) that there is a unique stationary solution of equation (1) for $\{Y_n\}$ in terms of the white noise sequence $\{Z_n\}$ if and only if $\phi(z)$ is nonzero for all complex z such that $|z| = 1$. The solution is

$$Y_n = \sum_{j=-\infty}^{\infty} \sigma \psi_j Z_{n-j} \quad (2)$$

where $\psi(z) := \sum_{j=-\infty}^{\infty} \psi_j z^j$ is the Laurent expansion of $\theta(z)/\phi(z)$, valid in an annulus of the form $|z - 1| < \delta$. If, in addition, the reciprocals $\xi_1, \dots, \xi_p$ of the zeros of the polynomial $\phi(z)$ satisfy

$$|\xi_r| < 1, \quad r = 1, \dots, p \quad (3)$$

then $\psi_j = 0$ for $j < 0$ and $\{Y_n\}$ is said to be a *causal function* of $\{Z_n\}$. Since, from a second-order point of view, i.e., taking into account the first- and second-order moments of $\{Y_n\}$ only, every noncausal ARMA(p, q) process can be written as a causal function of a different standard white noise process, attention is usually restricted to processes defined by equation (1) with condition (3) satisfied. We can then write

$$Y_n = \sum_{j=-\infty}^n g_{n-j} Z_j \quad (4)$$

where $\psi(z) := \sum_{j=0}^{\infty} \psi_j z^j = \theta(z)/\phi(z)$, $|z| \leq 1$, and

$$g_j = \sigma \psi_j, \quad j = 0, 1, 2, \dots \quad (5)$$

The sequence $\{g_j\}$ is called the *kernel* or *absolutely summable linear filter* relating the ARMA process $\{Y_n\}$ to $\{Z_n\}$. In all that follows, we shall assume causality so that the representation (4) holds with g_j given by equation (5).

If we suppose, in addition, that the sequence $\{Z_t\}$ is an independent and identically distributed (iid) sequence, then $\{Y_n\}$ is said to be a *strict* ARMA process. In this case, $\{Y_n\}$ is a *strictly stationary* process, i.e., for each positive integer n and for each $(t_1, \dots, t_n)$, the joint distribution of $(Y_{t_1+h}, \dots, Y_{t_n+h})$ is independent of h .

The ARMA process defined by equation (1) has an equivalent and illuminating *state-space representation*, specified by the equations,

$$Y_n = \sigma \theta' \mathbf{X}_n \quad (6)$$

and

$$\mathbf{X}_{n+1} - \Phi \mathbf{X}_n = \mathbf{e} Z_{n+1} \quad (7)$$

where

$$\Phi = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ \phi_r & \phi_{r-1} & \phi_{r-2} & \cdots & \phi_1 \end{bmatrix},$$

$$\mathbf{e} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}, \quad \boldsymbol{\theta} = \begin{bmatrix} \theta_{r-1} \\ \theta_{r-2} \\ \vdots \\ \theta_1 \\ \theta_0 \end{bmatrix}$$

$r := \max(p, q + 1)$, $\theta_0 := 1$, $\theta_j := 0$ for $j > q$ and $\phi_j := 0$ for $j > p$. The causality condition (3) implies that the eigenvalues of the matrix Φ are all less than 1 in absolute value so that the state-vector $\mathbf{X}_t$ has the representation,

$$\mathbf{X}_n = \sum_{j=-\infty}^n \Phi^{n-j} \mathbf{e} Z_j \quad (8)$$

Equations (6) and (8) show that the kernel sequence $\{g_j\}$ in the representation (4) can also be written as

$$g_j = \sigma \boldsymbol{\theta}' \Phi^j \mathbf{e}, \quad j = 0, 1, 2, \dots \quad (9)$$

From equations (4) and (9) we easily find that $EY_n = 0$ and

$$\gamma_Y(h) := \text{Cov}(Y_{t+h}, Y_t) = \sigma^2 \boldsymbol{\theta}' \Phi^{|h|} \Xi \boldsymbol{\theta} \quad (10)$$

where $\Xi = E[\mathbf{X}_t \mathbf{X}_t'] = \sum_{j=0}^{\infty} \Phi^j \mathbf{e} \mathbf{e}' \Phi'^j$. The ARMA process, as we have defined it, has mean 0. We can, of course, easily extend the definition by saying that $\{U_n\}$ is an ARMA process with mean μ if $\{U_n - \mu\}$ is a zero-mean ARMA process.

Remark 1 In the case when $p > q$ and the reciprocals, $\xi_1, \dots, \xi_p$, of the zeros of the polynomial $\phi(z)$ are distinct, it follows from equations (4) and (9) and the spectral representation of the matrix Φ , that $\{Y_n\}$ has a *canonical representation* as a linear combination of (possibly complex-valued) ARMA(1,0) processes, $\{Y_{r,n}\}$. Thus

$$Y_n = \sum_{r=1}^p \beta_r Y_{r,n} \quad (11)$$

where $Y_{r,n} = \sum_{j=-\infty}^n \xi_r^{n-j} Z_j$ and $\beta_r = -\sigma \xi_r \theta(\xi_r^{-1}) / \phi'(\xi_r^{-1})$. Notice that the driving white noise sequence is the same for each of the component processes $\{Y_{r,n}\}$, so they are not independent. Corresponding to the canonical decomposition (11), there is an analogous representation of the autocovariance function, namely,

$$\gamma_Y(h) = \sum_{j=1}^p \gamma_j \xi_j^{|h|}, \quad (12)$$

where $\gamma_j = -\sigma^2 \xi_j \theta(\xi_j) \theta(\xi_j^{-1}) / [\phi(\xi_j) \phi'(\xi_j^{-1})]$.

Remark 2 Parallel to the *time domain* representation (4) of $\{Y_n\}$, there is a *spectral* or *frequency domain* representation,

$$Y_n = \int_{-\pi}^{\pi} \sigma \frac{\theta(e^{-i\omega})}{\phi(e^{-i\omega})} e^{i\omega n} dZ(\omega) \quad (13)$$

where $\{Z(\omega), -\pi \leq \omega \leq \pi\}$ is an orthogonal increment process with mean 0 and $E|dZ(\omega)|^2 = d\omega / (2\pi)$, and the autocovariance function has the corresponding spectral representation $\gamma_Y(h) = \int_{-\pi}^{\pi} f(\omega) e^{ih\omega} d\omega$, where the spectral density function f is given by

$$f(\omega) = \frac{\sigma^2}{2\pi} \left| \frac{\theta(e^{-i\omega})}{\phi(e^{-i\omega})} \right|^2, \quad \omega \in [-\pi, \pi] \quad (14)$$

Remark 3 So far we have considered only second-order properties of $\{Y_n\}$. If we make the stronger assumption that the driving white noise sequence is iid with log characteristic function, $\log E \exp(i\omega Z_n) = \xi(\omega)$, and if $t_1, \dots, t_n$ are integers such that $t_1 < t_2 < \dots < t_n$ and $\omega_1, \dots, \omega_n \in \mathbf{R}$, then we can use the representation (4) to derive the log of the joint characteristic function,

$$\begin{aligned} \log E \exp(i \sum_{r=1}^n \omega_r Y_{t_r}) \\ = \sum_{k=0}^{n-1} \sum_{j=t_{n-k-1}+1}^{t_{n-k}} \xi \left(\sum_{r=0}^k \omega_{n-r} g_{t_{n-k}-j} \right) \end{aligned} \quad (15)$$

where $t_0 := -\infty$.

CARMA Processes

A natural analog, in continuous time, of the stochastic difference equation (1) is the stochastic differential equation,

$$a(D)Y(t) = \sigma b(D)DL(t) \quad (16)$$

where σ is a strictly positive scale parameter, D denotes differentiation with respect to t , $a(z) := z^p + a_1 z^{p-1} + \dots + a_p$, $b(z) := b_0 + b_1 z + \dots + b_{p-1} z^{p-1}$, and the coefficients b_j satisfy $b_q = 1$ and $b_j = 0$ for $q < j < p$. To avoid trivial and easily eliminated complications, we shall assume that $a(z)$ and $b(z)$ have no common factors.

The continuous-time analogs of the driving noise terms Z_n in equation (1) are the increments of the process L . We shall assume that L is a Lévy process on $(-\infty, \infty)$, i.e., a process with homogeneous independent increments, continuous in probability, with cadlag sample-paths and $L(0) = 0$. We shall also restrict attention to second-order Lévy processes, i.e., those satisfying the condition $E(L(1)^2) < \infty$, and suppose, without further loss of generality, that $\text{Var}L(1) = 1$ and $EL(t) = \mu t$ for some $\mu \in \mathbb{R}$. The increments of L on disjoint intervals of equal length are then iid random variables with finite variance and some infinitely divisible distribution which could, for example, be Gaussian, gamma, compound Poisson, inverse Gaussian, or one of many other possibilities.

Since the derivatives on the right of equation (16) do not exist in the usual sense, we write the equation in state-space form (cf. equations (6) and (7)),

$$Y(t) = \sigma \mathbf{b}' \mathbf{X}(t) \quad (17)$$

and

$$d\mathbf{X}(t) - \mathbf{A}\mathbf{X}(t) dt = \mathbf{e} dL(t) \quad (18)$$

where

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 1 \\ -a_p & -a_{p-1} & -a_{p-2} & \dots & -a_1 \end{bmatrix},$$

$$\mathbf{e} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} b_0 \\ b_1 \\ \vdots \\ b_{p-2} \\ b_{p-1} \end{bmatrix}$$

with solution satisfying

$$\mathbf{X}(t) = e^{A(t-s)} \mathbf{X}(s) + \int_s^t e^{A(t-u)} \mathbf{e} dL(u), \quad \text{for all } t > s \quad (19)$$

In the Gaussian case L is Brownian motion, equation (18) is interpreted as an Ito equation and the integral in equation (19) is an Ito integral. In the general case, the integral in equation (19) is defined as in [12].

If we restrict attention to causal solutions, i.e., if we make the assumption that $\mathbf{X}(s)$ is independent of $\{L(t) - L(s), t > s\}$ for every s , then necessary and sufficient conditions for the existence of a strictly stationary process $\mathbf{X}$ satisfying equation (19) (see [6]) are

$$\text{Re}(\lambda_r) < 0, \quad r = 1, \dots, p \quad (20)$$

and, under these conditions, the stationary solution must satisfy

$$\mathbf{X}(t) \text{ is distributed as } \int_0^\infty e^{A u} \mathbf{e} dL(u) \text{ for all } t \quad (21)$$

where $\lambda_1, \dots, \lambda_p$ are the eigenvalues of A (which are also the zeros of the autoregressive polynomial $a(z)$). Condition (21) specifies the stationary marginal distribution of $\mathbf{X}(t)$ and condition (20) is the continuous-time analog of the causality condition (3).

If we assume that the conditions (20) and (21) hold, and let $s \rightarrow -\infty$ in equation (19) we find that

$$\mathbf{X}(t) = \int_{-\infty}^t e^{A(t-u)} \mathbf{e} dL(u) \quad (22)$$

Conversely, if $\mathbf{X}(t)$ is defined by equation (22) then $\mathbf{X}$ is a strictly stationary causal process satisfying equation (19). Consequently, $\{\mathbf{X}(t)\}$ as defined in equation (22) is the unique, strictly stationary causal function of L satisfying equation (19).

We now define the strictly stationary causal CARMA process by equation (17) with $\mathbf{X}$ given by equation (22). Thus,

$$Y(t) = \int_{-\infty}^t \sigma \mathbf{b}' e^{A(t-u)} \mathbf{e} dL(u) \quad (23)$$

This is the continuous-time analog of equation (4) with the discrete-time kernel, $\{g_j = \sigma \theta' \Phi^j \mathbf{e}, j = 0, 1, 2, \dots\}$, replaced by the continuous-time kernel,

$$g(t) = \sigma \mathbf{b}' e^{At} \mathbf{e}, \quad t > 0 \quad (24)$$

From equation (23), we find that $EY(t) = \sigma \mu b_0/a_p$ (where $\mu = EL(1)$) and

$$\gamma_Y(h) := \text{Cov}[Y(t+h), Y(t)] = \sigma^2 \mathbf{b}' e^{A|h|} \Sigma \mathbf{b} \quad (25)$$

where $\Sigma = E[\mathbf{X}(t)\mathbf{X}(t)'] = \int_0^\infty e^{Ay} \mathbf{e} \mathbf{e}' e^{A'y} dy$.

Remark 4 If the zeros, $\lambda_1, \dots, \lambda_p$, of the polynomial $a(z)$ are distinct, it follows from equation (23) and the spectral representation of the matrix A that $\{Y_n\}$ has a *canonical representation* as a linear combination of (possibly complex-valued) CARMA(1,0) processes, $\{Y_r(t)\}$. Thus,

$$Y(t) = \sum_{r=1}^p \beta_r Y_r(t) \quad (26)$$

where $Y_r(t) = \int_{-\infty}^t e^{\lambda_r(t-u)} dL(u)$ and $\beta_r = \sigma b(\lambda_r)/a'(\lambda_r)$. Notice that the driving process L is the same for each of the component processes $\{Y_r(t)\}$, so they are not independent. Corresponding to the canonical decomposition (26), there is an analogous representation of the autocovariance function, namely,

$$\gamma(h) = \sum_{r=1}^p \gamma_r e^{\lambda_r |h|} \quad (27)$$

where $\gamma_r = \sigma^2 b(\lambda_r) b(-\lambda_r) / [a(-\lambda_r) a'(\lambda_r)]$.

Remark 5 The mean-corrected process $\{Y^*(t) = Y(t) - \sigma \mu b_0/a_p\}$ has a spectral representation

$$Y^*(t) = \int_{-\infty}^{\infty} \sigma \frac{b(i\omega)}{a(i\omega)} e^{i\omega t} dZ(\omega) \quad (28)$$

where $\{Z(\omega), -\infty < \omega < \infty\}$ is an orthogonal increment process with mean 0 and $E|dZ(\omega)|^2 = d\omega/(2\pi)$, and the autocovariance function of Y (and of Y^*) has the corresponding spectral representation $\gamma_Y(h) = \int_{-\infty}^{\infty} f(\omega) e^{i\omega h} d\omega$, where the spectral density function f is given by

$$f(\omega) = \frac{\sigma^2}{2\pi} \left| \frac{b(i\omega)}{a(i\omega)} \right|^2, \quad \omega \in (-\infty, \infty) \quad (29)$$

Gaussian processes with such rational spectral densities were discussed extensively in [9].

Remark 6 If $\log E \exp(i\omega L(1)) = \xi(\omega)$, and if $t_1, \dots, t_n$ satisfy $t_1 < t_2 < \dots < t_n$ and $\omega_1, \dots, \omega_n \in \mathbf{R}$, then from the representation (23),

$$\begin{aligned} \log E \exp(i \sum_{r=1}^n \omega_r Y(t_r)) \\ = \sum_{k=0}^{n-1} \int_{t_{n-k-1}}^{t_{n-k}} \xi \left(\sum_{r=0}^k \omega_{n-r} g(t_{n-r} - u) \right) du \end{aligned} \quad (30)$$

where $t_0 := -\infty$.

Prediction and Inference

From observations at discrete times, $t_1 < t_2 < \dots < t_{k-1}$, of either an ARMA or CARMA process $\{Y(t)\}$ with specified parameter values, various techniques are available for computing the minimum mean-squared error linear predictor,

$$\hat{Y}(t_k) = \alpha_{k,0} + \alpha_{k,1} Y(t_{k-1}) + \dots + \alpha_{k,k-1} Y(t_1) \quad (31)$$

of $Y(t_k)$, $t_k > t_{k-1}$, and its mean-squared error, $v_k = E(Y(t_k) - \hat{Y}(t_k))^2$. For details see, for example [5] and [11]. If we assume that the series is Gaussian, we can write the joint density of $(Y(t_1), \dots, Y(t_n))$ at $(y(t_1), \dots, y(t_n))$ as

$$g(y(t_1), \dots, y(t_n)) = \prod_{k=1}^n \frac{1}{\sqrt{v_k}} f \left(\frac{y(t_k) - m(t_k)}{\sqrt{v_k}} \right) \quad (32)$$

where f is the standard normal density function, $m(t_k) = \alpha_{k,0} + \alpha_{k,1} y(t_{k-1}) + \dots + \alpha_{k,k-1} y(t_1)$ for $k > 1$, $m_1 = EY(t)$ and $v_1 = \text{Var}(Y(t))$. For given values of p and q , maximum Gaussian likelihood (MGL) estimators of the parameters are obtained by maximizing g with respect to the process parameters. This is a nonlinear maximization problem, and requires the use of efficient numerical techniques. Many other estimation procedures are available, with varying asymptotic efficiencies, but it is known that under rather mild conditions and even when the process $\{Y(t)\}$ is not in fact Gaussian, MGL estimators

have good asymptotic properties. Model selection, i.e., choice of p and q , is usually made by minimization of an information criterion, well-known examples being the AIC, AICC, and BIC. See [5] and [10] for details.

Some Extensions and Applications

One of the features frequently observed in financial and geophysical time series is the very slow rate of decay with increasing lag of the sample autocorrelation function. In order to model this phenomenon, *fractionally integrated* ARMA and CARMA processes were introduced. These have the property that the autocorrelation function decreases asymptotically at a hyperbolic rate, rather than at the exponential rate of decay for both ARMA and CARMA processes. For information on fractionally integrated processes see [2, 6, 8].

Nonlinear generalizations of ARMA and CARMA processes, in particular threshold models (see [14]), have also found a wide variety of applications.

In mathematical finance, the CARMA(1,0) (or stationary Ornstein–Uhlenbeck) process, driven by a nondecreasing Lévy process, has been used to represent stochastic volatility in the stochastic volatility model of Barndorff-Nielsen and Shephard [1]. Higher order CARMA models for stochastic volatility have also been used to allow for more complex autocorrelation functions (see [4] and [13]). In the COGARCH models of (see Further Reading), the volatility process is a nonlinear self-exciting CARMA process and for COGARCH models in which the volatility process has finite variance, the volatility has the autocorrelation function of a CARMA process, a property analogous to the corresponding result for the volatility of a GARCH process, which, if the volatility has finite variance, has the autocorrelation function of an ARMA process.

Copulas in Econometrics

Copulas and Multivariate Models

The knowledge of the multivariate (conditional) distribution (especially fat tails, asymmetry, positive or negative dependence) is essential in many important financial applications, including portfolio selection, option pricing, asset pricing models, Value-at-Risk (market risk, credit risk, liquidity risk) calculations, and forecasting. Copulas provide a general, flexible tool in modeling the complex dependence structure among multiple random variables and in building multivariate models from univariate models; see [6, 20, 26] for discussions and references on the applications of copulas in economics, finance, insurance, and risk management. Patton [23] provides an excellent review of copula models for financial time series.

A copula is a multivariate distribution function with uniform marginal distributions on $[0, 1]$ that links together univariate distribution functions to form a multivariate distribution function. To simplify the exposition, the focus is on the bivariate case in this article. Let X, Y denote two scalar random variables with the joint distribution function H and marginal distribution functions F, G . The characterization theorem of Sklar [25] implies that there exists a copula $C(u, v)$: $(u, v) \in [0, 1]^2$ such that

$$H(x, y) = C(F(x), G(y)) \text{ for all } (x, y) \in \mathcal{R}^2 \quad (1)$$

Conversely, for any marginal distributions F, G and any copula function C , the function $C(F(\cdot), G(\cdot))$ is a bivariate distribution function with given marginal distributions F, G . This theorem provides the theoretical foundation for the widespread use of copulas in generating multivariate distributions (models) from univariate distributions (models).^a The fact that the copula function C , the marginal distribution functions F, G in equation (1) are not necessarily of the same type allows the researcher a great deal of flexibility in specifying a multivariate distribution (model). For example, Chen and Fan [2] propose a general class of multivariate dynamic time series models by first modeling each individual time series by a univariate generalized autoregressive conditional heteroskedasticity (GARCH)-type model and then modeling the joint distribution of the innovations of the univariate models by a distribution with

a parametric copula and unknown marginal distributions. We refer the reader to [2] for details and related references.

Suppose that X, Y are continuous random variables. Then the copula function C in equation (1) is unique.^b It extracts the dependence information on X, Y from their joint distribution H and is sometimes referred to as the *dependence function of X, Y* . The copula function of X, Y is invariant to monotone increasing transformations of X, Y and most rank dependence measures can be expressed in terms of the copula alone, including Kendall's τ , Spearman's ρ , and tail dependence coefficients; for details, see [17] and [22]. It is to be noted, however, that Pearson's linear correlation coefficient cannot be expressed in terms of the copula alone; it also depends on the marginal distributions.

Suppose that the density function of (X, Y) exists and is denoted by h . Then equation (1) implies

$$h(x, y) = f(x)g(y)c(F(x), G(y)) \quad \forall (x, y) \in \mathcal{R}^2 \quad (2)$$

where f, g are the marginal density functions and c is the copula density function. The decomposition of the joint density function h in equation (2) is the basis for the commonly used methods for estimating copula models. For a fully parametric copula model in which both the copula function and the marginal distribution functions are parameterized, both maximum likelihood (ML) method and two-step method can be used. Joe [17] and Nelsen [22] present numerous parametric copula functions including the Gaussian copula, Student's t copula, and Archimedean copulas. For a semiparametric copula model in which the copula function is parameterized, but the marginal distribution functions are not, both two-step method and sieve ML method have been developed; see [15] for details on the two-step method and [5] for details on the sieve ML method. To introduce the two-step approach and ML or sieve ML approach, suppose that we have a random sample $\{X_i, Y_i\}_{i=1}^n$ from $h(x, y)$. Then equation (2) implies that the log-likelihood function is given as

$$\begin{aligned} \sum_{i=1}^n \ln f(X_i) + \sum_{i=1}^n \ln g(Y_i) \\ + \sum_{i=1}^n \ln c(F(X_i), G(Y_i)) \end{aligned} \quad (3)$$

In the two-step approach, the marginal distribution functions F and G are estimated in the first step and the copula function is estimated in the second step. For example, for a semiparametric copula model, the marginal distribution functions are estimated in the first step by the corresponding (rescaled) empirical distribution functions denoted as $\hat{F}(x)$, $\hat{G}(y)$ and the copula function is estimated in the second step by maximizing $\sum_{i=1}^n \ln c(\hat{F}(X_i), \hat{G}(Y_i))$. We refer the reader to [15] for details on the two-step approach for random samples and [2, 3] for extensions to copula-based multivariate and univariate time series models, respectively. In the ML or sieve ML approach, the marginal distribution functions and the copula function are estimated simultaneously. For a fully parametric copula model, this is accomplished by maximum likelihood estimation (MLE) obtained from maximizing the log-likelihood function (3) with respect to parameters in both the marginal distribution functions and the copula function simultaneously, whereas for a semiparametric copula model, the maximization of the log-likelihood function (3) is carried out over respective sieve spaces approximating the spaces of marginal distribution functions F and G and the parameter space for the copula parameter; see [5] for details on sieve spaces and the sieve MLE. In general, the two-step estimator is asymptotically less efficient than the ML estimator in a parametric copula model or the sieve ML estimator in a semiparametric copula model.

In a parametric or semiparametric copula model in which the copula is parameterized, it is important to select an appropriate parametric copula and to evaluate how well the selected copula model fits the data at hand. Commonly used parametric copula families include the Gaussian copula family, Student's t copula family, Gumbel copula family, Clayton copula family, and Frank copula family. The latter three copula families are members of the general Archimedean copula family. These copula families have different dependence properties and are thus appropriate for modeling different dependence properties of economic and financial variables. For example, the Gaussian and Frank copula families have no tail dependence and are thus not appropriate for modeling financial variables that tend to take extreme values together. Instead, Student's t copula family has both lower and upper tail dependence and thus is appropriate for modeling economic or financial variables taking extremely large or small values together. On the

other hand, the Gumbel copula family has upper tail dependence and no lower tail dependence, whereas the Clayton copula family has lower tail dependence and no upper tail dependence. Chen and Fan [2, 4] developed model selection tests for copula families and [13], among others, developed goodness-of-fit tests for copulas. For applications of estimation and model selection procedures for copula-based models, the reader is referred to [4, 7]. Additional references can be found in [23].

The General Fréchet Problem

In addition to its role in building multivariate models from univariate models, copulas have also proven to be useful in finding solutions to the general Fréchet problem. Broadly speaking, the Fréchet problem concerns the problem of finding sharp bounds on the distributions of functions of random variables X, Y such as $X + Y$ and $X - Y$ when the marginal distribution functions F, G are fixed. The reader is referred to [24, 27] for discussions and references on the general Fréchet problem and its solutions, to [20] for its applications in finance and risk management, and to [11, 12] for its applications in program evaluation.

For $(u, v) \in [0, 1]^2$, let $C^L(u, v) = \max(u + v - 1, 0)$ and $C^U(u, v) = \min(u, v)$ denote the Fréchet–Hoeffding lower and upper bounds for a copula, that is, $C^L(u, v) \leq C(u, v) \leq C^U(u, v)$. Then for any $(x, y) \in \mathcal{R}^2$, the following inequality holds:

$$C^L(F(x), G(y)) \leq H(x, y) \leq C^U(F(x), G(y)) \quad (4)$$

The bivariate distribution functions $C^L(F(\cdot), G(\cdot))$ and $C^U(F(\cdot), G(\cdot))$ are referred to as the *Fréchet–Hoeffding lower and upper bounds* for bivariate distribution functions with fixed marginal distributions F and G . They are distributions of perfectly negatively dependent and perfectly positively dependent random variables respectively; see [22] for more discussions. The inequality (4) directly implies sharp bounds on the correlation coefficient between X and Y : $\rho_L \leq \rho \leq \rho_U$, where

$$\rho_L = \frac{\int \int [C^L(F(x), G(y)) - F(x)G(y)] dx dy}{\sigma_X \sigma_Y}$$

$$\rho_U = \frac{\int \int [C^U(F(x), G(y)) - F(x)G(y)] dx dy}{\sigma_X \sigma_Y} \quad (5)$$

in which σ_X^2 and σ_Y^2 are variances of X and Y , respectively. It is known that ρ_L and ρ_U are sharp; see [9, 20] for detailed discussions on this result and other properties and pitfalls of the correlation coefficient as a dependence measure.

Although inequality (4) does not directly imply bounds on distribution functions of $X + Y$ and $X - Y$, copulas provide a useful tool in finding such bounds; see [14]. In what follows, sharp bounds on the distribution function of $X - Y$ and sharp bounds on the quantile function of $X + Y$ are provided and their applications pointed out.

Let $\Delta = X - Y$. Δ is referred to as the *individual treatment effect* in the literature on program evaluation. In this context, X is the potential outcome from treatment and Y is the potential outcome without treatment; see [11, 12] for details. Denote the distribution function of Δ by $F_\Delta(\cdot)$. Given the marginals F and G , sharp bounds on the distribution of Δ can be found in [27]: $F_\Delta^L(\delta) \leq F_\Delta(\delta) \leq F_\Delta^U(\delta)$, where

$$\begin{aligned} F_\Delta^L(\delta) &= \sup_y \max(F(y) - G(y - \delta), 0), \\ F_\Delta^U(\delta) &= 1 + \inf_y \min(F(y) - G(y - \delta), 0) \end{aligned} \quad (6)$$

Let $\Lambda = X + Y$ and $Q_\Lambda(p)$ ($= F_\Lambda^{-1}(p)$) denote its generalized quantile function at quantile level p : $0 < p < 1$. Given the generalized quantile functions F^{-1} and G^{-1} , sharp bounds on $Q_\Lambda(p)$ can be found in [20, 27]: $Q_\Lambda^L(p) \leq Q_\Lambda(p) \leq Q_\Lambda^U(p)$, where

$$\begin{aligned} Q_\Lambda^L(p) &= \inf_{u \in [p, 1]} [F^{-1}(u) + G^{-1}(u - p + 1)], \\ Q_\Lambda^U(p) &= \sup_{u \in [0, p]} [F^{-1}(u) + G^{-1}(u - p)] \end{aligned} \quad (7)$$

McNeil *et al.* [20] discuss applications of equation (7) in risk management and provide an extensive list of references.

The expressions in equations (5)–(7) share one common feature, that is, they depend only on the marginal distributions. As a result, they can be consistently estimated without requiring any dependence

information between X and Y , provided that univariate samples from F, G are available. For example, consider a linear portfolio Λ of market risk X and credit risk Y . Estimation of the Value-at-Risk of Λ requires a bivariate sample from the joint distribution of X, Y , which may not always be available. In contrast, equation (7) implies that the smallest and largest Value-at-Risk can be estimated with univariate samples from F, G . Inference on ρ , $F_\Delta(\delta)$, and $Q_\Lambda(p)$ belongs to the recent, but fast-growing area in econometrics, namely, inference for partially identified parameters. The reader is referred to [10] for discussion and references.

Conclusion

This article concludes with a mention of some recent work on the construction of higher dimensional copulas and the Fréchet problem in higher dimensions. Copulas have found to be most successful in bivariate modeling, as there are numerous parametric families of bivariate copulas that the researcher can choose from; see [17, 22]. Compared with bivariate parametric copulas, the number of higher dimensional parametric copulas is rather limited. So far, most applications in higher dimensions have focused on Gaussian copulas and Student's t copulas. It is well known that the construction of higher dimensional copulas is very difficult. Several methods have been proposed recently, including methods for constructing higher dimensional Archimedean copulas and the general pair-copula construction approach known as *vines*; see [1, 19] and the references therein.

The Fréchet problem in higher dimensions has drawn attention recently. The reader is referred to [8] for a brief account and references. Finally, the reader is referred to [21] and the associated discussions and rejoinder for a lively discussion on the value of copulas in multivariate modeling.

End Notes

^aJoe [17] and Nelsen [22] provide a detailed introduction to copulas and their mathematical and statistical foundations. Kallsen and Tankov [18] present a version of Sklar's theorem that allows to construct a general multivariate Lévy process from arbitrary univariate Lévy processes and an arbitrary Lévy copula.

^bGenest and Nešlehová [16] present an excellent discussion on copulas for discrete data.

Measurements Errors

In physical sciences, errors in measurement are present everywhere owing to the unavoidable inaccuracy of the measuring devices, and most often they are thought of as being independent and centered variables, usually with a density, and which add up to the “true” values of the quantity of interest. In finance, the quantities of interest are usually prices, which can be exactly observed by virtually any person. Some factual errors, like wrong records, may occur, but those are relatively infrequent and easy to detect (giving rise to the “cleaning” of data), and may be modeled with independent centered variables with no density and a rather large mass at 0 (= no error).

However, mathematical models in finance are often continuous-time models describing the dynamics of a process $(X_t : t \geq 0)$. This process is the basic underlying “price”, or log-price, of an asset, or several assets if it is multivariate, and it satisfies the rules of mathematical finance, and, in particular, it is a semimartingale by the first fundamental theorem of asset pricing. This process cannot be exactly observed because (i) any observed price is an integer (a number of elementary units, like a cent or a hundredth of a cent); and (ii) one may think that extraneous reasons, like some erratic behavior of price makers or erratic orders, “locally” change the price in a way that does not affect the underlying and should not influence the model for it.

In practice, one then observes prices Z_t that are possibly different from the underlying, or “efficient”, prices X_t , and at finitely many times $t_0, t_1, \dots, t_n$. This may look like an academic difference and it may appear that, in practice, we ought to consider Z_t and not X_t at all. However, currently we have high-frequency or very high-frequency data, like tick data, and it is empirically clear that we need to differentiate between X_t and Z_t . For example, when $Z_t = X_t$ (no error), the so-called realized volatility, which is the sum

$$V_n = (Z_{t_1} - Z_{t_0})^2 + (Z_{t_2} - Z_{t_1})^2 + \dots + (Z_{t_n} - Z_{t_{n-1}})^2 \quad (1)$$

is a quantity that converges, when the observations become more and more frequent over a fixed time interval $[0, T]$, to a given quantity V (the integrated

volatility over $[0, T]$ when X_t is continuous, and, more generally, to the quadratic variation of the process X_t). Moreover, at least when observation times are equidistant or almost equidistant, the “rate of convergence” is $\sqrt{n}$, which means that $\sqrt{n} (V_n - V)$ does neither explode nor go to 0 (and in fact it usually converges to some limit). Now, all empirical studies show that V_n increases indefinitely when the frequency of observations increases: this goes back to [15] and [8], or more recently to, for example, [2] or [12]. Hence, the observations Z_t differ from the underlying X_t in a nonnegligible way, and the difference $\epsilon_t = Z_t - X_t$ is referred to as the *microstructure noise*, or *market frictions*, and should be taken into account.

We then have to give a model for this microstructure noise, on top of the semimartingale model for X_t , like Black–Scholes, possibly with stochastic volatility, or jump diffusion, or others. The microstructure noise models that have been proposed so far in the literature are mostly the following:

1. The errors ϵ_t are independent, centered, identically distributed variables, and also independent of the underlying X_t . This is the simplest and most well-understood situation, in which the uncorrected realized volatility V_n increases to ∞ at the rate n . When the efficient price X_t is continuous and one is interested in estimating the integrated volatility V over $[0, T]$, that is, the quadratic variation of X_t at time T , a variety of variants of V_n have been proposed, using various smoothing kernels: the best methods give a rate of convergence which is $n^{1/4}$, known as the *optimal rate* when X_t is a Brownian motion, and asymptotic variances which are nearly optimal. Note that no distributional assumption is made on the errors, and, in particular, the variance of the errors is not supposed to be known.

Such results can be extended to (i) errors that are not independent, but present some sort of “weak” dependence, and are still globally independent of X_t ; (ii) errors that are not identically distributed, provided their second moments stay constant; (iii) errors that are multiplicative instead of additive, meaning that the variables Z_t/X_t are independent instead of the $Z_t - X_t$, and “centered” is replaced by “with mean 1”. The literature about this question is huge, and among many articles we can quote [1, 3–6, 13, 14, 16, 17].

2. The previous models more or less take care of reason (ii) for microstructure noise. As for reason (i), and if it were the only reason for the noise, one should simply take the observation Z_t to be $Z_t = \alpha[X_t/\alpha]$, where $[x]$ denotes the integer part of any number x , and α is the precision with which prices are written (1 cent or 1/100 cent for example). Then again some results for the estimation of the integrated volatility V are available, asymptotically when n increases whereas the rounding level α decreases to 0. Very few papers have been devoted so far to this subject; see, for example, [7].
3. Now, with the frequency attained by observations of prices, one cannot satisfactorily consider that the rounding level α is “small”, and we have a serious problem here: if α is fixed and the frequency increases, then the realized volatility increases to ∞ with the rate $\sqrt{n}$, and the integrated volatility is no longer identifiable. The best one can know about the process X_t is the times at which it crosses the level $i\alpha$ for any integer i , or equivalently the family of so-called “local times” $L(i\alpha)$ at levels $i\alpha$ for all integers i (and time T , the time horizon). This is very far from V , although V is indeed the limit of $\alpha \sum_{i \geq 0} L(i\alpha)$ as $\alpha \rightarrow 0$ (see [9]).
4. In practice, models like (1) above are not fully satisfactory because they do not account for the—obvious and ubiquitous—fact that rounding-off occurs. Models like (2) with a fixed level α are not satisfactory either, on a mathematical level (they do not permit to retrieve the quantities of interest like V) and on an empirical level they give rise to sequences of prices that stay constant for relatively many successive times and then oscillate wildly between two adjacent multiples of α , then stay constant again: this is not quite observed in practice; usually prices stay constant for a few successive times, with occasionally a jump back and forth of one unit. Probably a more reasonable model consists in a mixture of (1) and (2): we have additive errors ϵ_t , and then rounding, that is, we observe $Z_t = \alpha[(X_t + \epsilon_t)/\alpha]$. It turns out—perhaps surprisingly—that if the errors ϵ_t have a density that is positive on an arbitrarily located interval of length at least α , then it is possible to retrieve the integrated volatility V in pretty much the same way as when rounding

is absent, and at the same rate. Some recent attempts in this direction may be found in [11] and [10].

5. One might also look for more microeconomically oriented models. That is, in addition to the rounding effect, which is probably unavoidable, one tries to model the behavior of the various agents so that the observed prices Z_t behave according to empirical data, whereas the underlying X_t , which is a sort of “local limit” of the Z_t ’s, satisfies a model that fits the usual requirements of mathematical finance (no-arbitrage, completeness, and so on). This looks like the two-scale diffusions, but so far this has not really been put in use, because of the mathematical difficulties, and even more because the underlying microeconomics is still at a rather rudimentary level.

JEAN JACOD

Time Change

The mathematical concept of time-changing continuous-time stochastic processes has first been studied in [11, 17, 18, 23, 24, 29, 39] and has later been introduced to the finance literature in [14]. Today, it can be regarded as one of the standard tools for building financial models (see also [22, 32]).

Let $X = (X_t)_{t \geq 0}$ denote a stochastic process, sometimes referred to as the *base process*, and let $T = (T_s)_{s \geq 0}$ denote a nonnegative, nondecreasing stochastic process not necessarily independent of X . The *time-changed process* is then defined as $Y = (Y_s)_{s \geq 0}$, where

$$Y_s = X_{T_s} \quad (1)$$

The process X is said to evolve in *operational time*. The process T is referred to as a *time change*, *stochastic clock*, *chronometer*, or *business time*. It reflects the varying *speed* of Y .

This article is structured as follows. First we link the use of time-changed stochastic processes to the construction of univariate stochastic volatility models in finance. Then we focus on the choice of an appropriate base process and, next, on popular examples for the time change. Finally, we briefly discuss the potential and the limitations of the methodology of time-changing stochastic processes to construct multivariate models in finance.

Stochastic Volatility Models

The use of time-changed stochastic processes in finance is closely linked to the concept of stochastic volatility models for asset prices. Numerous empirical studies have revealed the fact that asset price volatility tends to be time varying and tends to show clustering effects. The concept of stochastic volatility (see **Volatility**) in continuous-time asset price models on a filtered probability space $(\Omega, \mathcal{A}, (\mathcal{F}_t)_{t \geq 0}, \mathbb{P})$ can basically be introduced by two methods.

One of the methods is to use time-changed stochastic processes as in equation (1), where natural assumptions are that $X = (X_t)_{t \geq 0}$ is an $\mathcal{F}_t$ -semimartingale and $(T_s)_{s \geq 0}$ is an increasing family of $\mathcal{F}_t$ -stopping times. The base process X is often assumed to possess some homogeneity properties,

whereas a nonlinear time change can induce deviations from homogeneity.

The other method is to use stochastic integrals (see **Stochastic Integrals**) of the form

$$Y_t = \int_0^t \sigma_{r-} dX_r \quad (2)$$

where $\sigma = (\sigma_t)_{t \geq 0}$ is a nonnegative $\mathcal{F}_t$ -predictable stochastic volatility process and $X = (X_t, t \geq 0)$ is an $\mathcal{F}_t$ -semimartingale. Often, X is assumed to possess some homogeneity properties so that nonconstant σ can induce deviations from homogeneity.

Under certain conditions, the models (1) and (2) lead to equivalent models. However, in general, this is not true, and we highlight in the following text some of the main differences between these two modeling approaches.

Time-changed Lévy Processes

In the finance literature, the main focus is on time-changed Brownian motion or, more generally, on time-changed Lévy processes (see **Lévy Processes**; **Time-changed Lévy Process**), since these processes possess natural homogeneity properties of stationary and independent increments (returns).

Time-changed Brownian motion has first been used as a model for (logarithmic) asset prices by Clark [14]. He investigated the case where $X = B = (B_t)_{t \geq 0}$ is a standard Brownian motion and where T is an independent continuous-time change. Clearly, in such a setting, the time-changed process $Y_s = B_{T_s}$ has a mixed normal distribution, that is, $Y_s | T_s \sim N(0, T_s)$, and is a continuous local martingale. The power of such models and those with the assumptions of independence and/or continuity relaxed is expressed in the following key results.

Theorem 1 (*Dubins–Schwarz*). [18, 34, 35] *Every continuous local martingale $M = (M_s)_{s \geq 0}$ can be written as a time-changed Brownian motion $(B_{[M]_s})_{s \geq 0}$, where $[M] = ([M]_s)_{s \geq 0}$ is the (continuous) quadratic variation of M .*

Also $M_t = \int_0^t \sigma_{r-} dW_r$ for $X = W = (W_t)_{t \geq 0}$ Brownian motion and $\sigma = (\sigma_t)_{t \geq 0}$ independent nonnegative with càdlàg sample paths is a continuous local martingale with quadratic variation $[M]_t =$

$[\int_0^t \sigma_r dW_r]_t = \int_0^t \sigma_r^2 dr$, which is often referred to as *integrated variance*.

Corollary 1 *In the context of the Dubins–Schwarz theorem, for the local martingale $M_s = \int_0^s \sigma_r dW_r = B_{[M]_s}$, independence of W and σ is equivalent to independence of B and $T = [M]$.*

Therefore, the models (1) and (2) are equivalent if X is a Brownian motion and $T_s = \int_0^s \sigma_r^2 dr$ is an absolutely continuous time change. Regarding Clark’s independence assumption, we note that independence of σ and X is also equivalent in models (1) and (2); however, this excludes the leverage effect, that is, the usually negative correlation between asset returns and volatility.

Fundamentally, these results are due to the scaling property of Brownian motion X , which translates spatial scaling σX_t or model (2) into temporal scaling $X_{\sigma^2 t}$ or model (1). Also, if Brownian motion is replaced by an α -stable Lévy process and $T_t = \int_0^t \sigma_s^\alpha ds$, the two models (1) and (2) are basically equivalent [25, 26]. No other Lévy process has such a scaling property, and indeed, the models (1) and (2) will be different. If we relate higher volatility to higher market activity, then model (1) suggests that markets move at a higher speed, and model (2) suggests that the volumes traded are higher.

Theorem 2 (Monroe [33]). *Every (càdlàg) semimartingale $Z = (Z_s)_{s \geq 0}$ can be written as a time-changed Brownian motion $(B_{T_s})_{s \geq 0}$ for a (càdlàg) family of stopping times $(T_s)_{s \geq 0}$ on a suitably extended probability space.*

In the light of the fundamental theorem of asset pricing (see **Fundamental Theorem of Asset Pricing**), this means that every arbitrage-free model can be viewed as time-changed Brownian motion. However, this result is of limited use for the construction of simple and natural parametric models.

In the finance literature, we find many asset price models where the base process is chosen to be a Lévy process other than Brownian motion (see, e.g., [12, 13]). Here, we refer to **Time-changed Lévy Process** for a detailed treatment of this class of models.

We also mention Lamperti’s representations [27, 28] of continuous-state branching processes and of self-similar Markov processes as time-changed Lévy processes very much in the spirit of the

Dubins–Schwarz Theorem. Salminen and Yor [36] use Lamperti’s time change to study Dufresne’s functional [20] that arises in the computation of discounted values in certain models of continuously payable perpetuities in actuarial science.

Choice of Time Change

There are different methods for choosing a time change that is suitable for financial models. Two classes of such processes are particularly popular: subordinators and absolutely continuous time changes [1].

In the finance literature, the terms *time change* and *subordinator* are sometimes used synonymously. However, in probability theory, the term subordinator describes a particular class of stochastic processes (as defined below) and does not include all time changes.

Subordinators

Subordinators are nondecreasing Lévy processes [10, 15, 37] and hence possess stationary and independent increments. They are pure jump processes of possibly infinite activity plus a deterministic linear drift. Clearly, they have no Brownian component and are of finite variation. Important examples include simple Poisson processes, increasing compound Poisson processes, gamma processes, and (tempered) stable subordinators. Note that many popular models in finance are based on time-changed Brownian motion where the time change is chosen to be a subordinator. For example, the variance gamma process [30, 31] can be represented as Brownian motion time-changed by a gamma process, the normal tempered stable process (including the normal inverse gaussian process [2, 3]) can be written as a Brownian motion time-changed by a tempered stable subordinator. Brownian motion, time-changed by an independent subordinator, yields a Lévy process always.

Absolutely Continuous Time Changes

Another important class of time changes is given by the class of absolutely continuous time changes of the form $T_s = \int_0^s \tau_u du$, for a positive and integrable process $\tau = (\tau_s)_{s \geq 0}$. Note that in such a setting T is always continuous, but τ can exhibit jumps. The process τ is often called *instantaneous (business)*

activity rate. Such models have been studied in the context when X is a Lévy process by Carr *et al.* [12] and [13] among others. The advantage of this model class is that it leads to affine models that are highly analytically tractable (see, e.g., [19, 25]), whereas stochastic integrals with respect to Lévy processes are in general not affine. Popular examples for the instantaneous activity rate are given by the Cox–Ingersoll–Ross process and the non-Gaussian Ornstein–Uhlenbeck process [7, 8, 16].

Multivariate Setting

Time-changed stochastic processes are also used in the finance literature to construct multivariate models. Usually, the base process X is then assumed to be multivariate (e.g., a multivariate Brownian motion) and the time-change process T is still assumed to be univariate ([15, 21] and the references therein). The advantage of such a modeling framework is the fact that such processes are highly analytically tractable and easy to simulate from. However, the range of dependence between the univariate components in such a multivariate model is rather limited (and, in particular, does not even include complete independence). Furthermore, such a model does not allow for an arbitrary choice of univariate models for the components [15]. The mathematical properties of multivariate processes X time-changed by a multivariate vector of time changes T have recently been studied in [5], but this has so far not been considered as a standard tool for constructing multivariate models in finance. So far, it has been much more common to use multivariate extensions of a stochastic integral (2) to construct multivariate stochastic volatility models, than to use time-changed processes. Finally, note that the concept of subordinators can also be generalized to matrix subordinators [4, 6] and their applicability in financial models is subject to ongoing research (see, e.g., [9, 38] for some first references).

Stylized Properties of Asset Returns

Since prices of different stocks are not necessarily influenced by the same events or information sets, price series obtained from different assets and—*a fortiori*—from different markets may exhibit different (statistical) properties. After all, why should properties of corn futures be similar to those of IBM shares or the dollar/yen exchange rate? Nevertheless, the result of more than half a century of empirical studies on financial time series indicates that this is the case if one examines their properties from a *statistical* point of view. The seemingly random variations of asset prices *do* share some nontrivial statistical properties. Such properties, common across a wide range of instruments, markets, and time periods, are called *stylized empirical facts* [10].

This assertion is backed by a vast research literature dealing with the statistical properties of financial time series which has developed during the last 50 years. Some early references include [25, 26, 29]. Surveys of stylized facts of financial time series are given in [17] for foreign exchange rates and in [5, 8, 10, 16, 30] for stocks and indices. Scaling and time-aggregation properties for high-frequency data are studied in [2] for stocks and in [17, 18, 27, 28] for foreign exchange rates. Numerous empirical studies on the scaling properties of returns can also be found in the physics literature [7].

Stylized facts are thus obtained by taking a common denominator among the properties observed in studies of different markets and instruments. Obviously, by doing so one gains in generality but tends to lose in the precision of the statements one can make about asset returns. Indeed, stylized facts are usually formulated in terms of *qualitative properties* of asset returns and may not be precise enough to distinguish among different parametric models. Nevertheless, albeit qualitative, these stylized facts are so constraining that it is not even easy to exhibit an (*ad hoc*) stochastic process which possesses the same set of properties, and stochastic modeling has gone to great lengths to reproduce these stylized facts.

Stylized facts are usually formulated in terms of asset (log-)returns defined as

$$r_t(\Delta) = \ln \frac{S_{t+\Delta}}{S_t} \quad (1)$$

where S_t is the price of an asset at date t and Δ is a time horizon. The properties of returns series $r_t(\Delta)$ greatly depend on the sampling frequency, that is, on Δ .

We focus here on empirical properties for *daily* (log-)returns of stocks and stock market indices in liquid markets and refer to **High-frequency Data** and **Market Microstructure Effects** for properties of intraday data.

1. **Heavy tails:** The (unconditional) distributions of returns display—at time horizons ranging from an hour to several weeks—heavy tails and positive sample excess kurtosis, properties that both reject the Gaussian assumption (Figure 1). A more precise formulation requires measuring the heaviness of the tails. For heavy tails with “regular variation” (*see Extreme Value Theory*), that is, of the type

$$P(r_t \geq x) = \frac{l_+(x)}{|x|^{\alpha_+}}, \quad P(r_t \leq x) = \frac{l_-(x)}{|x|^{\alpha_-}} \quad (2)$$

where l_+ (respectively l_-) is slowly varying at $+\infty$ (respectively $-\infty$) and $\alpha_+, \alpha_- > 0$ are the (right/left) tail exponents, the heaviness of the tails can be measured by the value of α_+, α_- . $\xi_+ = 1/\alpha_+$ is sometimes called the (right) *tail index*. Light tailed distributions with exponential-type tail have a zero tail index, while a strictly positive tail index indicates heavy tails of regularly varying type. Tail exponents can be estimated using a Hill estimator or using methods based on the extreme value theory (*see Extreme Value Theory*). Figure 2 shows the estimation of right and left tail indices for SP100 daily returns: in this example we find $\alpha_+ \simeq 4$ and $\alpha_- \simeq 3$. For stock and index returns, tail exponents are often found to be finite, higher than two and less than five for most data sets studied [20, 23, 24]. In particular, this excludes stable laws with infinite variance and the normal distribution. Power-law or Pareto tails reproduce such behavior. But, as argued, for example, in Heyde and Kou [19], with small samples exponential tails (“semi-heavy tails”) may be difficult to distinguish from Pareto tails.

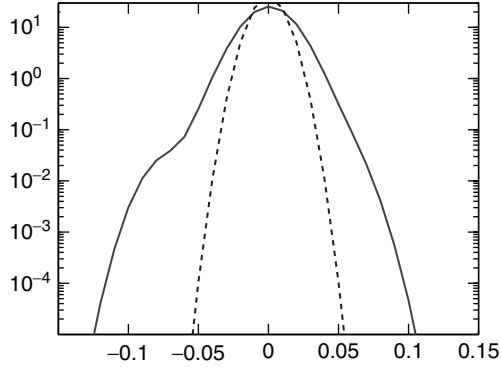

Figure 1 Kernel estimator of empirical density of SP100 daily returns (solid line) vs Gaussian density (dotted line) with same mean and variance, on a logarithmic scale. Note the dominance of the tails with respect to the Gaussian and the asymmetry of the empirical density

2. **Absence of autocorrelations:** (Linear) autocorrelations of asset returns are often insignificant, except at short lags ($\simeq 10$ min) for which microstructure effects come into play (*see Market Microstructure Effects*). Figure 3 illustrates this fact for the yen–US dollar exchange rate. This absence of significant autocorrelation can be attributed to the existence of arbitrageurs who “whiten the spectrum of price changes”, making their second-order properties indistinguishable from a white noise sequence [26]. A consequence of this absence of autocorrelation is the additivity of variance or “square-root” scaling rule: the variance of returns at horizon $n\Delta$ is n times the variance at horizon Δ in the absence of autocorrelations; thus the standard deviation should be scaled by $\sqrt{n}$. This scaling is the basis of the variance ratio test

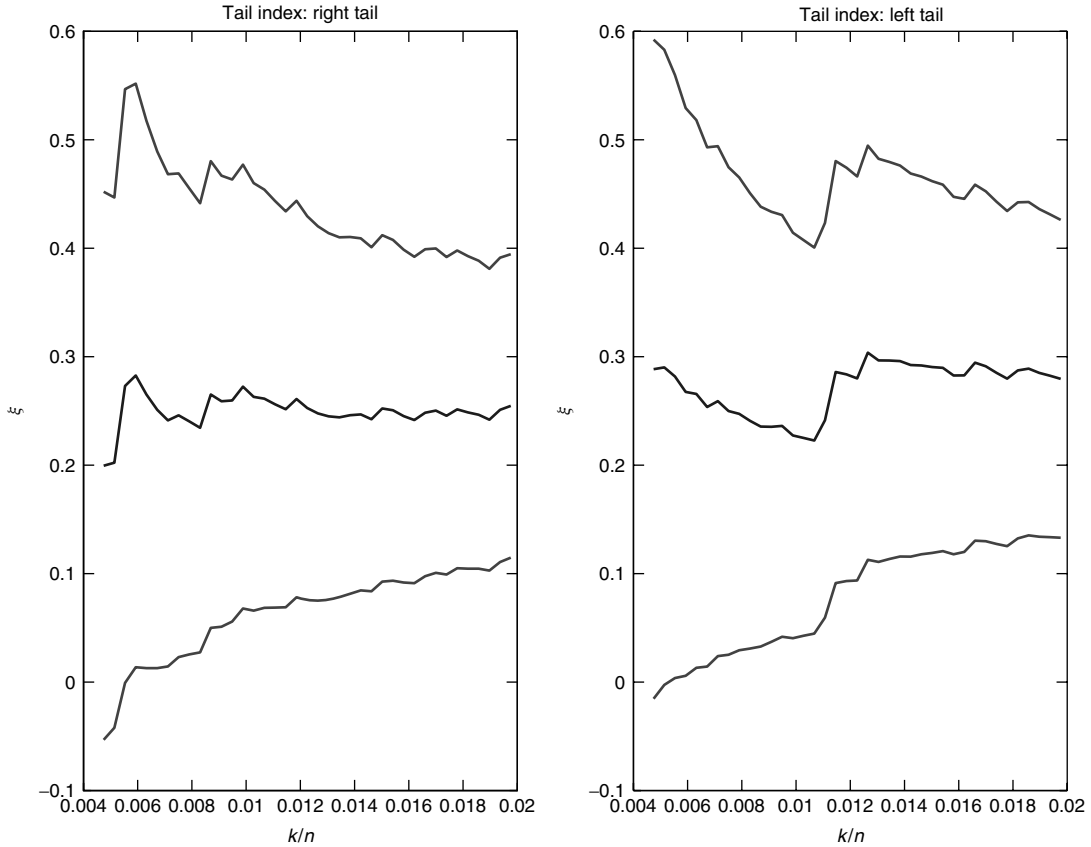

Figure 2 Hill estimators for the tail index of SP100 daily returns. We obtain $\alpha_+ \simeq 4$ and $\alpha_- \simeq 3$. Note the large standard errors

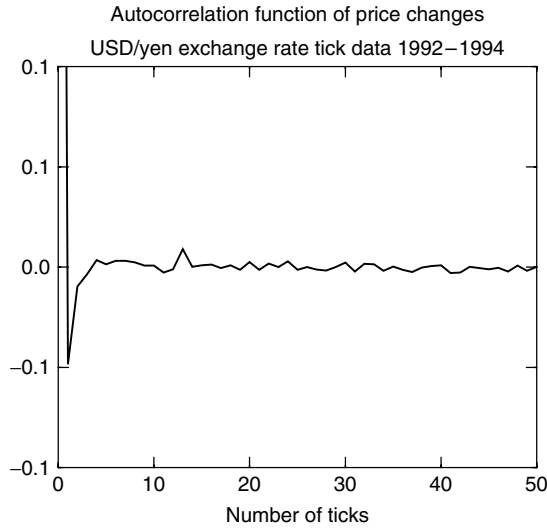

Figure 3 Autocorrelation function of log-returns, USD/yen exchange rate, $\Delta = 5$ min

for autocorrelation [8]. Note that this scaling rule breaks down for illiquid assets for which one typically observes high autocorrelation of returns.

3. **Gain/loss asymmetry:** Unconditional distributions of stock returns are often asymmetric. Although, this asymmetry may go undetected, when using moment-based measures such as skewness, one often observes a left tail which is heavier than the right tail, as attested by the tail index (*see Heavy Tails*) or extremal index (*see Extreme Value Theory*) estimates [20, 24]. For exchange rates between major currencies, there is a higher symmetry in up/down moves and the skewness can change sign from one period to another.

Daily changes in credit spreads (e.g., credit default swap spreads, *see Credit Default Swaps*) show an opposite asymmetry: they exhibit a heavier right (upper) tail and there are more frequent large upward jumps in credit spreads.

4. **Aggregational normality:** As one increases the timescale Δ over which returns are calculated, their distribution looks more and more like a normal distribution. In particular, the shape of the distribution is not the same at different timescales: the heavy-tailed feature

becomes less pronounced as the time horizon is increased.

5. **Volatility clustering:** “Large changes tend to be followed by large changes, of either sign, and small changes tend to be followed by small changes” [25]. A quantitative manifestation of this fact is that, while returns themselves are uncorrelated, absolute returns $|r_t(\Delta)|$, their squares, as well as other implied or historical volatility indicators display a positive, significant, and slowly decaying autocorrelation function. In particular, this observation rules out the assumption of independence of returns and points to nonlinear dependence in returns across time.

This property is sometimes called the “ARCH effect” in the econometrics literature, because of the fact that ARCH models (*see GARCH Models*) have this property. This is a misnomer: volatility clustering is a model-free property of data that has nothing to do with ARCH models.

6. **Conditional heavy tails:** Even after adjusting returns for volatility clustering (i.e. normalizing returns by a dynamic estimator of volatility, such as in GARCH-type models), the residuals (normalized returns) still exhibit heavy tails [5, 14]. However, the tails are less heavy than in the unconditional distribution of returns.

This remark has motivated the development of conditionally heteroskedastic models driven by non-Gaussian noise in discrete time and Lévy-driven stochastic volatility models in continuous time [4, 5, 13, 14] (*see GARCH Models; Jump Processes; Time-changed Lévy Process; Regime-switching Models*).

7. **Slow decay of autocorrelation in absolute returns:** The autocorrelation function of absolute (or squared) returns decays slowly as a function of the time lag, roughly as a power-law with an exponent $\beta \leq 1$. An example is shown in Figure 4. This is sometimes interpreted as a sign of long-range dependence in volatility (*see Long Range Dependence; Multifractals*).

It has been argued [4, 22] that the decay of the autocorrelation of $|r_t|$ can also be reproduced by a superposition of several exponentials, indicating that the dependence is characterized by multiple timescales. In fact, an operational definition of long-range dependence is that the timescale of dependence in a sample of length

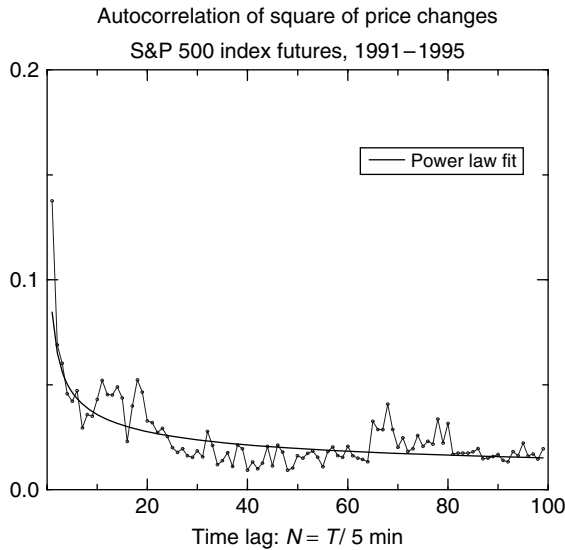

Figure 4 Autocorrelation function of squared log-returns: S&P500 futures, $\Delta = 30$ min

T is found to be of the order of T : dependence extends over the whole sample. Interestingly, the largest timescale in [22] is found to be of the order of the sample size, a prediction which would be compatible with long-range dependence [11].

8. **“Leverage” effect:** Volatility increases when the stock price falls. More precisely, changes in implied or historical indicators of volatility of an asset are negatively correlated with the returns of that asset. In fact, there is evidence of a lead–lag relationship: a negative correlation between *past* returns and (current) changes in volatility [6].

The name “leverage effect” comes from a supposed explanation based on a firm’s capital structure: a decrease in the market valuation of a firm’s equity increases the degree of leverage in its capital structure, leading to an increase in stock volatility. However, empirical studies do not seem to confirm this “explanation” [3] and the “leverage effect” should be seen more in terms of an asymmetric impact of news on returns and volatility [15].

9. **Volume–volatility correlation:** Trading volume in a given period (e.g., daily trading volume) is positively correlated with measures of volatility (e.g., realized volatility on the same day).

The same holds for other measures of market activity such as the number of trades.

These observations have motivated the construction of models in which the dynamics of prices is modeled as a function of cumulative volume [9] or number of transaction, and has inspired models based on time-changed processes (*see Time-changed Lévy Process; Mixture of Distribution Hypothesis; Time Change*).

10. **Asymmetry in time scales:** Volatility indicators computed at lower frequency predict future volatility at higher frequency, whereas past values of high-frequency volatility indicators do not necessarily have predictive power for future low-frequency volatility [18]. This observation has led to the development of “random cascade” models, in which market shocks affect price behavior at low frequencies (fine scales) and their impact trickles down to lower scales (*see Multifractals; [27]*).

It may be noted that we have not included “self-similarity” or scale invariance among the above properties. In fact, there is ample empirical evidence showing that asset returns are *not* scale invariant or self-similar [12]. For example, the shape of the distribution of returns $r_t(\Delta)$ at a horizon Δ greatly varies with Δ and “scales” in a nontrivial way, which is not captured by simple self-similar models such as α -stable Lévy processes (*see Lévy Processes*) or (fractional) Brownian motion (*see Fractional Brownian Motion*).

Stylized Facts as Model Benchmarks

Stylized empirical facts have motivated research in two different directions. One is the development of stochastic models—in discrete or continuous time—whose aim is to match some or all of the observed properties of financial time series. For instance, the (G)ARCH family of models (*see GARCH Models*) was mainly developed to model volatility clustering and heavy tails in asset returns, while stochastic volatility models were developed to model volatility clustering and the leverage effect. Similarly, models based on Lévy processes (*see Exponential Lévy Models*) were initially introduced to capture the time-aggregation properties (heavy tails

at high-frequency, scaling with respect to the horizon Δ) of the distribution of returns.

Another strand of research has aimed at proposing economic explanations for the origins of stylized facts. Representative agent models attempt to explain stylized facts in terms of the behavior of a hypothetical representative investor whose behavior generates market price changes. Ait-Sahalia [1] shows that this approach can go a long way in terms of reproducing, if not explaining, stylized empirical facts. By contrast, agent-based market models [11, 21] tend to view stylized facts as properties *emerging* from the collective behavior of a large number of market participants. In all the cases, stylized empirical properties of asset returns serve as benchmarks for evaluating the plausibility of financial models before any estimation or testing is done.

Stochastic Volatility Models: Extremal Behavior

Extreme value theory for financial models mostly concerns the martingale (see **Martingales**) component of the logarithm of a price process, since random volatility determines the extreme risk in price fluctuations. The increments $(Y_n)_{n \in \mathbb{Z}}$ and $(Y_t)_{t \in \mathbb{R}}$ of length 1 of this martingale part often have the structure

$$Y_n = \sigma_n \varepsilon_n, \quad n \in \mathbb{Z}, \quad \text{or} \quad Y_t = \int_{(t-1, t)} \sigma_{s-} dL_s, \quad t \in \mathbb{R} \quad (1)$$

for a discrete-time or continuous-time model, respectively. Here, the volatility is modeled by σ , and $(\varepsilon_n)_{n \in \mathbb{Z}}$ or $(L_t)_{t \in \mathbb{R}}$ are typically independent and identically distributed (i.i.d.) sequences or a Lévy process (see **Lévy Processes**), respectively. The usual prerequisite of extreme value theory for a stochastic process is its strict stationarity. Note that, in most cases, strict stationarity of the log price increment process Y is inherited from stationarity of the volatility process σ . Consequently, we present conditions for strict stationarity of the models below, followed by the extremal analysis of a stationary version.

The importance of extreme value theory for such pricing models is twofold. First, the *tail behavior* for large absolute arguments describes the fluctuations of the prices. We distinguish between light- and heavy-tailed models: light tailed means normal or exponential models, whereas heavy-tailed models are defined *via* regular variation. We say a random variable X has regularly varying tail, if there are $\alpha > 0$ and slowly varying $\ell : (0, \infty) \rightarrow (0, \infty)$, that is, $\lim_{x \rightarrow \infty} \ell(tx)/\ell(x) = 1$ for all $t > 0$, such that

$$P(X > x) = \ell(x)x^{-\alpha}, \quad x > 0 \quad (2)$$

We write $X \in \mathcal{R}(-\alpha)$. If the volatility σ has regularly varying tail and the noise ε or L is light tailed and independent of the volatility, then the log price increments are again regularly varying by Breiman's classical result. The same holds for a light-tailed volatility and independent regularly varying noise. If both, volatility and noise, are light

tailed, the distribution of the product depends even asymptotically on both factors and may be more difficult to estimate. Symmetry or tail balance of the right and left tails of the noise often simplifies the calculations.

Second, *volatility clusters on high levels* induce extreme price clusters, which can cause a particularly risky situation. For discrete-time models, such clusters are described by a limit of point processes of exceedances over high thresholds. For certain models, this limit is simply a Poisson process, indicating that exceedances happen as single points and at completely random times. However, more realistic models capture the fact that the limit process is not a Poisson process but a compound Poisson process, which describes also the cluster size distribution. A crude, but simple, measure of the cluster size of extremes is the *extremal index* $\theta \in (0, 1]$, where $1/\theta$ can be interpreted as the mean size of a cluster. It also appears in the distributional limit of the running maxima

$$M_n^Z = \max\{Z_1, \dots, Z_n\}, \quad n \in \mathbb{N} \quad (3)$$

of a stationary sequence $(Z_n)_{n \in \mathbb{Z}}$. More precisely, under weak conditions on Z_1 , there exist $a_n > 0$ and $b_n \in \mathbb{R}$ such that the *Poisson condition*

$$nP(Z_1 > a_n x + b_n) = -\log G(x), \quad x \in \mathbb{R} \quad (4)$$

holds, and if the process satisfies further mixing conditions, then the extremal index of $(Z_n)_{n \in \mathbb{Z}}$ is the unique number $\theta \in (0, 1]$ such that

$$\lim_{n \rightarrow \infty} P(a_n^{-1}(M_n^Z - b_n) \leq x) = G^\theta(x), \quad x \in \mathbb{R} \quad (5)$$

Here, G is an extreme value distribution, that is, it is of the same type as a Fréchet distribution $\Phi_\alpha(x) = \mathbf{1}_{(0, \infty)}(x) \exp(-x^{-\alpha})$ for some $\alpha > 0$ (heavy-tailed case), a Gumbel distribution $\Lambda(x) = \exp(-e^{-x})$ (light-tailed case), or a Weibull distribution Ψ_α for some $\alpha > 0$. We refer to the books [11, 24] for this and further information about extreme value theory.

For $\theta = 1$, we interpret the stochastic process as a process without clusters in the extremes, whereas if $\theta < 1$ we speak of a process with cluster possibilities in the extremes. Using a point process approach, the whole cluster size distribution can be derived, giving

much more insight into the extremal behavior of time series models. This, however, would go beyond the scope of this article and we refer to the references given throughout for more details.

As for discrete-time models, the extremal behavior of continuous-time models can be described by the limit behavior of point processes. A simple measure is again given by an extension of the extremal index: if $(Z_t)_{t \in \mathbb{R}}$ is a continuous-time process, we define for fixed $h > 0$ the discrete-time process

$$M_k^Z(h) := \sup_{(k-1)h \leq t \leq kh} Z_t, \quad k \in \mathbb{Z} \quad (6)$$

Denoting $\theta(h)$ as the extremal index of the sequence $(M_k^Z(h))_{k \in \mathbb{Z}}$, we follow [13] and call $\theta(h)$ for $h \in (0, \infty)$ the *extremal index function* of Z . The function θ is increasing, and we shall say that the continuous-time process Z has extremal clusters if $\lim_{h \rightarrow 0} \theta(h) < 1$, that is, if there is some $h > 0$ such that the discrete skeleton $(M_k^Z(h))_{k \in \mathbb{Z}}$ has extremal index less than 1, that is, it clusters.

There exist various publications on extreme value theory for time-dependent data; we mention, for example, [7, 8, 11, 17–20, 24] and references therein.

Discrete-time Stochastic Volatility Models

The simple stochastic volatility model is given by

$$Y_n = \sigma_n \varepsilon_n, \quad \log \sigma_n^2 = \alpha_0 + \sum_{j=0}^{\infty} c_j \eta_{n-j}, \quad n \in \mathbb{Z} \quad (7)$$

where $(\eta_n)_{n \in \mathbb{Z}}$ is i.i.d. $N(0, s^2)$ with $\sum_{j=0}^{\infty} c_j^2 < \infty$ and $(\varepsilon_n)_{n \in \mathbb{Z}}$ is i.i.d., independent of $(\eta_n)_{n \in \mathbb{Z}}$. This covers the case when $(\log \sigma_n^2)_{n \in \mathbb{Z}}$ is a causal ARMA process with i.i.d. Gaussian noise $(\eta_n)_{n \in \mathbb{Z}}$, the most prominent case being the volatility model of Taylor [28]:

$$Y_n = \sigma_n \varepsilon_n, \quad \log \sigma_n^2 = \alpha_0 + \psi \log \sigma_{n-1}^2 + \eta_n, \quad n \in \mathbb{Z}, \quad |\psi| < 1 \quad (8)$$

when the log volatility is a causal Gaussian AR(1) process.

Extreme value analysis for equation (7) is based on the transformation

$$X_n = \log Y_n^2 = \alpha_0 + \sum_{j=0}^{\infty} c_j \eta_{n-j} + \log \varepsilon_n^2, \quad n \in \mathbb{Z} \quad (9)$$

which is a Gaussian linear process plus an i.i.d. noise. From [5, 7] we have the following theorem:

Theorem 1 (Tail Behavior and Extremes of the Stochastic Volatility Model). *Assume the stochastic volatility model (7) as above with X_n defined by equation (9).*

(a) *If ε_1 is $N(0, 1)$ denote $\tilde{s}^2 = s^2 \sum_{j=0}^{\infty} c_j^2$ and $k = \log(2/\tilde{s}^2)$.*

Then the tail of the stationary process $(X_n)_{n \in \mathbb{Z}}$ satisfies as $x \rightarrow \infty$

$$P(X_1 > x + \alpha_0) = \frac{\tilde{s}^2}{\sqrt{\pi}} \exp \left\{ -\frac{x^2}{2\tilde{s}^2} + \frac{x \log x}{\tilde{s}^2} + \frac{(k-1)x}{\tilde{s}^2} + \frac{(k+\tilde{s}^2) \log x}{\tilde{s}^2} - \frac{(\log x)^2}{2\tilde{s}^2} - \frac{k^2}{2\tilde{s}^2} + O\left(\frac{(\log x)^2}{x}\right) \right\} \quad (10)$$

The tail of the stationary log price increments is given by

$$P(Y_1 > \sqrt{y}) = \frac{1}{2} P(|Y_1| > \sqrt{y}) = \frac{1}{2} P(X_1 > \log y), \quad n \in \mathbb{Z} \quad (11)$$

If, furthermore, the autocorrelation function ρ of $(\log \sigma_n^2)_{n \in \mathbb{Z}}$ satisfies

$$\rho(h) = \text{corr}(\log \sigma_n^2, \log \sigma_{n+h}^2) = o((\log h)^{-1}), \quad h \rightarrow \infty \quad (12)$$

then each of the sequences $(X_n)_{n \in \mathbb{Z}}$ and $(Y_n)_{n \in \mathbb{Z}}$ has extremal index 1, and the extreme value distribution G appearing in equations (4) and (5) is the Gumbel distribution Λ for both X and Y .

(b) Assume that $\varepsilon_1 \in \mathcal{R}(-\alpha)$ for some $\alpha > 0$. Then as $x \rightarrow \infty$ we have

$$P(Y_1 > x) \sim E(\sigma_1^\alpha) P(\varepsilon_1 > x) \quad (13)$$

If, moreover, for $p \in (0, 1]$ the tail balance condition for $x \rightarrow \infty$ $P(\varepsilon_1 > x) \sim p P(|\varepsilon_1| > x)$ holds, then $(Y_n)_{n \in \mathbb{Z}}$ has extremal index 1 and the extreme value distribution G appearing in (4) and (5) is the Fréchet distribution Φ_α .

Here, $f(x) \sim g(x)$ as $x \rightarrow \infty$ for two strictly positive functions f and g means that $\lim_{x \rightarrow \infty} f(x)/g(x) = 1$. Berman's condition (12) is very weak and, for example, satisfied, whenever $\log \sigma_n^2$ follows a causal ARMA equation (in particular, for the volatility model (8) of Taylor). This means that for most stochastic volatility models (7) with Gaussian η and either light- or heavy-tailed noise ε , the extremal index is 1, so that the point processes of exceedances over high thresholds converge to a Poisson process. The model cannot model clusters of extremes.

Extensions of the η_n to non-Gaussian random variables in equation (7) have been considered. In most cases, the qualitative behavior remains the same provided that the processes σ and ε are independent and η_1 is light-tailed [9, 10, 22].

EGARCH model

A model related to stochastic volatility models is the EGARCH model of Nelson [26] given by

$$Y_n = \sigma_n \varepsilon_n, \quad \log \sigma_n^2 = \alpha_0 + \sum_{j=1}^{\infty} c_j g(\varepsilon_{n-j}), \quad n \in \mathbb{Z} \quad (14)$$

where $(\varepsilon_n)_{n \in \mathbb{Z}}$ is i.i.d. normal (or more generally follows a generalized error distribution $\text{GED}(\nu)$), the real coefficients α_0 and $(c_j)_{j \in \mathbb{N}}$ decay sufficiently fast, and g is a deterministic function. The infinite moving average representation for $\log \sigma^2$ typically arises from EGARCH(p, q) equations of the form

$$\log \sigma_n^2 = \alpha_0 + \sum_{j=1}^p \alpha_j g(\varepsilon_{n-j}) + \sum_{j=1}^q \beta_j \log(\sigma_{n-j}^2) \quad (15)$$

with real coefficients α_j and β_j . The standard choice for g is $g(x) = \varphi x + \gamma(|x| - E|\varepsilon_0|)$, where φ and γ are real constants, so that g is an affine linear function and $g(\varepsilon_n)$ allows the volatility to respond asymmetrically to negative and positive innovations. Depending on the size of φ and γ , different cases arise, but the most important one is for $\gamma - \varphi > \gamma + \varphi > 0$, in which case a negative innovation increases the volatility more than a positive innovation of the same modulus (i.e., it models the leverage effect).

As for stochastic volatility models, extreme value analysis for equation (14) is based on the transformed process (which is stationary by equation 14)

$$\begin{aligned} X_n &= \log Y_n^2 \\ &= \alpha_0 + \sum_{j=1}^{\infty} c_j g(\varepsilon_{n-j}) + \log \varepsilon_n^2, \quad n \in \mathbb{Z} \end{aligned} \quad (16)$$

The following theorem follows from [9, 10, 22]:

Theorem 2 (Tail Behavior and Extremes of EGARCH). Assume the EGARCH model as above with $(\varepsilon_n)_{n \in \mathbb{N}}$ i.i.d. $N(0, 1)$ and $\gamma - \varphi > \gamma + \varphi > 0$. Suppose further that the coefficients $(c_j)_{j \in \mathbb{N}}$ are nonnegative and that $c_j = O(j^{-\delta})$ as $j \rightarrow \infty$ for some $\delta > 1$. Denote

$$A := (\gamma - \varphi)^2 \sum_{j=1}^{\infty} c_j^2 \quad \text{and} \quad B := -\gamma E|\varepsilon_0| \sum_{j=1}^{\infty} c_j \quad (17)$$

Then the stationary processes $(X_n)_{n \in \mathbb{Z}}$ and $(Y_n)_{n \in \mathbb{Z}}$ satisfy, as $x \rightarrow \infty$,

$$\begin{aligned} P(X_1 > \alpha_0 + x) &= \exp(-[x^2 - x \log x \\ &\quad - (B + \log(2/A) - 1)x]/A + o(x)) \end{aligned} \quad (18)$$

and (11), respectively. Both processes $(X_n)_{n \in \mathbb{Z}}$ and $(Y_n)_{n \in \mathbb{Z}}$ have extremal index 1, and the extreme value distribution G appearing in equation (4) and (5) is the Gumbel distribution.

Observe that for an EGARCH(p, q) process as in equation (15) with $\alpha_1, \dots, \alpha_p, \beta_1, \dots, \beta_q \geq 0$ and such that $\sum_{j=1}^q \beta_j < 1$, the coefficients $(c_j)_{j \in \mathbb{N}}$

in equation (14) are automatically nonnegative and decay exponentially, so that Theorem 2 applies. In particular, the EGARCH process with normal innovations cannot cluster. Extensions to other light-tailed innovations ε such as GED(ν) distributions with $\nu > 1$ are possible; cf [10].

GARCH(1,1) Model

In the GARCH(1,1) model (see **GARCH Models**) of Engle [12] and Bollerslev [4] the log price increments $(Y_n)_{n \in \mathbb{Z}}$ and the volatilities $(\sigma_n)_{n \in \mathbb{Z}}$ are given by

$$Y_n = \sigma_n \varepsilon_n, \quad \sigma_n^2 = \gamma + \alpha Y_{n-1}^2 + \beta \sigma_{n-1}^2, \quad n \in \mathbb{Z} \quad (19)$$

where $(\varepsilon_n)_{n \in \mathbb{Z}}$ are i.i.d. and $\alpha, \beta, \gamma > 0$. Rewriting

$$\sigma_{n+1}^2 = \gamma + (\alpha \varepsilon_n^2 + \beta) \sigma_n^2, \quad n \in \mathbb{Z} \quad (20)$$

it becomes clear that a stationary and causal solution exists if and only if $E \log(\alpha \varepsilon_1^2 + \beta) < 0$. The following result on the tail behavior is included in Kesten's seminal work; see [8] for further results and references. The calculation of the extremal index can be found in [19, 25].

Theorem 3 (Tail Behavior and Extremes of GARCH(1,1)). *Assume the GARCH(1,1) model such that ε_1 is symmetric and has a positive density on $\mathbb{R}$ such that $E(|\varepsilon_1|^h) < \infty$ for $h < h_0$ and $E(|\varepsilon_1|^{h_0}) = \infty$ for $h \geq h_0$ for some $h_0 \in (0, \infty]$. Then there exist unique $\kappa > 0$ and $c > 0$ such that*

$$E(\alpha \varepsilon_1^2 + \beta)^{\kappa/2} = 1 \quad (21)$$

and the stationary distributions have tails for $x \rightarrow \infty$

$$\begin{aligned} P(\sigma_1 > x) &\sim c x^{-\kappa} \quad \text{and} \\ P(Y_1 > x) &\sim \frac{1}{c} E(|\varepsilon_1|^\kappa) x^{-\kappa} \end{aligned} \quad (22)$$

The extremal indices of $(\sigma_n)_{n \in \mathbb{Z}}$ and $(|Y_n|)_{n \in \mathbb{Z}}$ are given by

$$\theta_\sigma = \int_1^\infty P \left(\sup_{n \geq 1} \prod_{j=1}^n (\alpha \varepsilon_j^2 + \beta) \leq y^{-1} \right)$$

$$\begin{aligned} &\times \frac{\kappa}{2} y^{-(\kappa/2)-1} dy \in (0, 1) \quad \text{and} \\ \theta_{|Y|} &= \frac{E \left(|\varepsilon_1|^\kappa - \sup_{m \geq 1} |\varepsilon_{m+1}|^\kappa \prod_{j=1}^m (\alpha \varepsilon_j^2 + \beta)^{\kappa/2} \right)^+}{E |\varepsilon_1|^\kappa} \\ &\in (0, 1) \end{aligned} \quad (23)$$

respectively. Also the extremal index $\theta_Y \in (0, 1)$, and for all three sequences σ , $|Y|$ and Y , the extreme value distribution G appearing in equations (4) and (5) is the Fréchet distribution Φ_κ .

We conclude that the GARCH(1,1) process is able to model clusters in the extremes. Extensions to higher order GARCH processes are given in [3, 8].

Continuous-time Models

While for discrete-time volatility models many results on the extremal behavior are formulated for both the volatility process and the log price increments process, with few exceptions, most of the literature on extremes for continuous-time models concentrates on the volatility process. Hence, in the following, we often state results concerning the volatility process only.

The Wiggins Model

In the volatility model of Wiggins [30] (see also [27]) the log volatility is modeled as a Gaussian Ornstein–Uhlenbeck (OU) process. More precisely, the log price increments Y_t and the volatility σ_t are given by

$$\begin{aligned} Y_t &= \int_{(t-1, t)} \sigma_s_- dB_s, \\ d \log \sigma_t^2 &= (b_1 - b_2 \log \sigma_t^2) dt + \delta dW_t, \\ t &\in \mathbb{R} \end{aligned} \quad (24)$$

with two independent standard Brownian motions B and W , and real constants b_1 , b_2 and $\delta \neq 0$. The volatility has a stationary solution if and only if $b_2 > 0$, in which case it is given by

$$\log \sigma_t^2 = \int_{-\infty}^t e^{-b_2(t-s)} (b_1 ds + \delta dW_s), \quad t \in \mathbb{R}$$

(25)

Sampling the log volatility at integer points results in a causal Gaussian AR(1) process, so that the Euler type approximation $\bar{Y}_n := \sigma_{n-1}(B_n - B_{n-1})$ to equation (24) is the discrete-time volatility model (8) of Taylor.

From the above representation, it is clear that $\log \sigma_t^2$ is $N(b_1/b_2, \delta^2/(2b_2))$ distributed. The extremal index function of $\log \sigma^2$ and hence σ^2 follows from results in [24] as shown in [13].

Theorem 4 (Extremal Index Function of the Volatility). *Under the assumptions above, the extremal index function $\theta_\sigma(h)$ for $h \in (0, \infty)$ of the stationary volatility process σ^2 in (24) is identical to 1.*

We conclude that the volatility in the model (24) does not allow for extremal clusters. This continues to hold if the Gaussian OU process for the log volatility in equation (24) is replaced by any Gaussian process with continuous sample paths satisfying equation (12). While it is easy to show that the stationary log price increment Y_1 in equation (24) is distributed as $\left(\int_0^1 \sigma_t^2 dt\right)^{1/2} \varepsilon_1$ with ε_1 standard normally distributed and independent of $(\sigma_t)_{t \in \mathbb{R}}$, we are not aware of any explicit expressions for the tail behavior and the extremal index function of Y_1 or $\log Y_1^2$ as in Theorem 1(a).

Barndorff-Nielsen and Shephard (BNS) Model

In [1, 2], Barndorff-Nielsen and Shephard (BNS) model (see **Barndorff-Nielsen and Shephard (BNS) Models**) the volatility process as a Lévy-driven OU process, which results in the model

$$\begin{aligned} Y_t &= \int_{(t-1, t)} \sigma_{s-} dB_s, \\ \sigma_t^2 &= \int_{-\infty}^t e^{-\lambda(t-s)} dL_{\lambda s}, \quad t \in \mathbb{R} \end{aligned} \quad (26)$$

where B is Brownian motion, $\lambda > 0$ and L is a Lévy process with increasing sample paths (i.e., a subordinator), independent of B . The volatility process is stationary and satisfies the stochastic differential equation (SDE) $d\sigma_t^2 = -\lambda\sigma_t^2 dt + dL_{\lambda t}$.

The extremal behavior of this model depends on the driving Lévy process and has been analyzed in

[13–15]. For regularly varying noise, as shown in [14], one obtains the following.

Theorem 5 (Tail and Extremes for Noise in $\mathcal{R}(-\alpha)$). *Consider the stationary BNS-model (26) and assume that $L_1 \in \mathcal{R}(-\alpha)$ with $\alpha > 0$. Then $\sigma_1 \in \mathcal{R}(-2\alpha)$, $Y_1 \in \mathcal{R}(-2\alpha)$ and we have for $x \rightarrow \infty$*

$$\begin{aligned} P(\sigma_1^2 > x) &\sim \alpha^{-1} P(L_1 > x) \\ P(Y_1^2 > x) &\sim E(|\varepsilon_1|^{2\alpha}) \left(\frac{(1 - e^{-\lambda})^\alpha}{\alpha \lambda^\alpha} \right. \\ &\quad \left. + \frac{1}{\lambda^\alpha} \int_0^1 (1 - e^{s-\lambda})^\alpha ds \right) P(L_1 > x) \\ P(Y_1 > x) &= \frac{1}{2} P(Y_1^2 > x^2) \end{aligned} \quad (27)$$

respectively, where ε_1 is a standard normal random variable. The extremal index function θ_σ of the volatility process is furthermore given by

$$\theta_\sigma(h) = (h\alpha\lambda)(h\alpha\lambda + 1)^{-1}, \quad h > 0 \quad (28)$$

Observe that for a regularly varying noise process, the tail of σ^2 is of the same order as that of the driving noise process. Also, since $\theta_\sigma(h) < 1$, the process exhibits cluster possibilities. This is in contrast to the case when L has exponential tail as in the next theorem; see [13, 18]:

Theorem 6 (Tail and Extremes for Exponential-type Noise). *Consider the stationary BNS-model (26) as above and assume that L_1 has an exponential-type distribution tail:*

$$\begin{aligned} P(L_1 > x) &= c(x) \exp \left\{ - \int_0^x (a(y))^{-1} dy \right\}, \quad x > 0 \end{aligned} \quad (29)$$

where $\lim_{x \rightarrow \infty} c(x) = c > 0$ and $a > 0$ is absolutely continuous with $\lim_{x \rightarrow \infty} a(x) = \gamma^{-1}$ and $\lim_{x \rightarrow \infty} a'(x) = 0$, where $\gamma \in [0, \infty)$. Assume also that $L_1 \in \mathcal{S}(\gamma)$, that is, $P(L_2 > x) \sim E(e^{\gamma L_1}) P(L_1 > x)$ as $x \rightarrow \infty$ with $E(e^{\gamma L_1}) < \infty$. Then

$$P(\sigma_1^2 > x) \sim \frac{a(x)}{x} \frac{E e^{\gamma \sigma_1^2}}{E e^{\gamma L_1}} P(L_1 > x), \quad x \rightarrow \infty \quad (30)$$

In particular, $P(\sigma_1^2 > x) = o(P(L_1 > x))$ for $x \rightarrow \infty$. The extremal index function θ_σ is equal to 1, that is, $\theta_\sigma(h) = 1$ for all $h > 0$.

Brockwell [6] suggests to model the volatility in equation (26) by Lévy-driven continuous-time ARMA (CARMA) processes, with the CAR(1) process being the OU process. As shown in [13–15], for CARMA processes driven by regularly varying noise processes, clusters occur as in Theorem 5, while for driving Lévy processes as described in Theorem 6, CARMA processes may or may not model clusters, depending on the corresponding kernel function. Todorov and Tauchen [29] suggest to model the volatility by a CARMA(2,1) process with a mixture of gamma distributions as driving noise process. For this model the results presented here do not apply.

Continuous-time GARCH(1,1) Models

As a diffusion limit of GARCH(1,1) processes, Nelson [26] obtained

$$\begin{aligned} Y_t &= \int_{(t-1,t)} \sigma_{s-} dB_s, \\ d\sigma_t^2 &= (\beta - \varphi\sigma_t^2) dt + \lambda\sigma_t^2 dW_t, \quad t \geq 1 \end{aligned} \quad (31)$$

where B and W are independent standard Brownian motions and $\beta \geq 0, \lambda > 0$ and $\varphi \in \mathbb{R}$ are parameters. It has a strictly stationary solution if and only if $2\varphi/\lambda^2 > -1$ and $\beta > 0$, in which case the marginal distribution is inverse gamma. The two independent driving processes in equation (31) are in contrast to the situation for discrete-time GARCH processes, where price and volatility are both driven by the same noise sequence $(\varepsilon_n)_{n \in \mathbb{Z}}$. Inspired by this, Klüppelberg *et al.* [23] constructed another continuous-time GARCH model, termed COGARCH(1,1), which meets the features of discrete-time GARCH better and for which the volatility jumps, unlike for the diffusion limit (31). Let $(L_t)_{t \geq 0}$ be a Lévy process with nonzero Lévy measure and $\eta, \varphi, \beta > 0$ be parameters. Defining the auxiliary Lévy process

$$R_t = \eta t - \sum_{0 < s \leq t} \log(1 + \varphi(\Delta L_s)^2), \quad t \geq 0 \quad (32)$$

the log price increments Y and the volatility σ are given by

$$\begin{aligned} Y_t &= \int_{(t-1,t)} \sigma_{s-} dL_s, \\ \sigma_t^2 &= \left(\beta \int_0^t e^{R_{s-}} ds + \sigma_0^2 \right) e^{-R_t}, \quad t \geq 1 \end{aligned} \quad (33)$$

where σ_0^2 is independent of L . A sufficient condition for strict stationarity of (33) is the existence of some $\kappa > 0$ such that

$$|L_1|^\kappa \log^+ |L_1| < \infty \quad \text{and} \quad E(e^{-R_1 \kappa/2}) = 1 \quad (34)$$

Observe that the volatility in Nelson's diffusion limit (31) has also a solution (33), with R_t defined by

$$R_t := (\varphi + \lambda^2/2)t - \lambda W_t, \quad t \geq 0 \quad (35)$$

For the stationary choice, we have

$$E(e^{-R_1 \kappa/2}) = 1 \quad \text{with} \quad \kappa := 2 + 4\varphi/\lambda^2 > 0 \quad (36)$$

The following result is from [16, 18]:

Theorem 7 (Tail and Extremes of Continuous-time GARCH). *Consider the stationary diffusion limit (31) or COGARCH(1,1) process as above with $\kappa > 0$ as given by equations (36) or (34), respectively. Then there exists a constant $c > 0$ such that*

$$P(\sigma_1 > x) \sim cx^{-\kappa}, \quad x \rightarrow \infty \quad (37)$$

In the case of the COGARCH(1,1) process, assume further that there is $d > \max\{1, \kappa\}$ such that $E|L_1|^{2d} < \infty$ with $\kappa > 0$ as defined in equation (34) and that L is not the negative of a subordinator. Denote $M_t := B_t$ for the diffusion limit (31) and $M_t := L_t$ for the COGARCH(1,1) process. Then

$$\begin{aligned} P(Y_1 > x) &\sim E \left[\left(\int_0^1 e^{-R_{t-}/2} dM_t \right)^+ \right]^\kappa \\ P(\sigma_1 > x), \quad x &\rightarrow \infty \end{aligned} \quad (38)$$

and σ has extremal index function

$$\theta_\sigma(h) = \frac{E \left(\sup_{0 \leq t \leq h} e^{-R_t \kappa/2} - \sup_{t \geq h} e^{-R_t \kappa/2} \right)^+}{E \left(\sup_{0 \leq t \leq h} e^{-R_t \kappa/2} \right)}$$

$$< 1, \quad h > 0 \quad (39)$$

The extremal index of the discrete-time process $(Y_n)_{n \in \mathbb{N}}$ of the log price increments at integer times is given by

$$\theta = \frac{E \left[(I_1^k - \max_{k \geq 2} I_k^k)^+ \right]}{E[I_1^k]} < 1 \quad (40)$$

It follows that both the diffusion limit and the COGARCH(1,1) can model extremal clusters. Since the diffusion limit (31) has continuous sample paths, one can also consider its clustering behavior via epsilon-upcrossings. Choosing such an approach, the diffusion limit of Nelson does not cluster, as reported in [18]. In particular, both notions of extremal clustering for processes with continuous sample paths do not lead to the same interpretation.

Similar to the definition of COGARCH, a continuous-time analog to the EGARCH process has been proposed in [21]. So far, no analog to Theorem 2 for the continuous-time EGARCH process seems to be available.

Securitization

Securitization is the process by which tradable securities are created and introduced into capital markets. Such a process generally involves, typically, the isolation of a pool of assets and their repackaging into securities. Securitization enables the originator of such a transaction to manage and diversify its risk, to optimize the use of capital, while investors in these new securities are looking for diversification and higher return. Various types of risks have been securitized and different structures have been issued in the capital markets.

Asset-backed Securities

The best-known example of securitization is certainly that of mortgages, with the first issue of mortgage-backed securities (MBS) taking place in 1970 in the United States. This transaction was the first of a very long series and the beginning of an extremely successful market. When the collateral of a securitization is made with more general assets than simple mortgages, the resulting securities are called *asset-backed securities (ABS)*. The collateral may be, for instance, credit card receivables or student loans.

As of January 1, 2006 [1], the estimated outstanding in the United States is \$8 trillion, which represents the largest segment of the American-fixed income market—31% of the total outstanding bond market (23% for the MBS and 8% for the ABS)—while the T-bond market only counts for 16%. The US market is the largest market in terms of securitization of mortgages in the world (80% of the total market). In Europe and Asia, the situation is slightly different since the legal framework for a securitization process to take place has been missing for a long time: new rules were adopted in the United Kingdom in 1987, in France in 1988, . . . , and in Italy only in 1999. In Asia, the first Indian ABS took place in 1992 (the first MBS in 2000), the first MBS took place in 1998 in Japan (Japan is the largest Asian market), 2005 in China, and 2003 in Taiwan.

Securitization of mortgages in the United States often require the participation of one of the three government sponsored enterprises (GSEs), the Federal National Mortgage Association (FNMA or Fannie

Mae), the Government National Mortgage Association (GNMA or Ginnie Mae), and the Federal Home Loan Mortgage Corporation (FHLMC or Freddie Mac). The securities backed by one of the GSEs are called *agency ABS*. Because of their government sponsorship (in particular that of the US Treasury), each of the GSEs could perfectly act as credit enhancer. Since most of the MBS are issued by these agencies, they implicitly have the full backing of the US treasury and therefore their credit risk is almost inexistent.

There are also ABS issued without the sponsorship of one of the GSEs. They are called *nonagency ABS*. In this case, the collateral is not standard. It is typically made of jumbo loans (i.e., huge mortgages with a rather good credit quality), Alt-A loans (i.e., loans where a borrower could not provide complete documentation of his assets or income), subprime loans (i.e., loans to borrowers with heavy credit burden and poor credit quality), or commercial loans (i.e., loans on retail, office, or industrial properties). Until the recent crisis of 2007, the subprime market was the largest part of the nonagency ABS. Several factors can explain their importance; in particular, the growing number of homeowners with heavy debt burden, the aggressiveness of the marketing of subprime issuers, and the lending practices in this market. The characteristics of the ABS with this nonstandard collateral are very different and make them attractive to investors: not only do they offer a higher yield to compensate for the higher credit risk but also the prepayment risk is typically very limited. Therefore, they offer an alternative with a different risk profile.

There are two main types of structures of ABS. The first type—*pass-through structures*—is the simplest. It corresponds to a securitization based directly on the collateral. The securities give a particular ownership right to the pool of *assets*. In this case, the cash flows of interest and principal received by the SPV are directly “passed through” to the investors. The investor receives a fraction of the payments on the pro rata of the number of shares he or she owns.

The second type—*pay-through structures*—is more complex. The securities, such as collateralized mortgage obligations (CMOs), are not directly based on the assets ceded by the originator and the securitization process requires some structuring. The SPV buys the collateral from the originator and then issues a variety of instruments, which divide

the collateral cash flows into different classes or *tranches*. Such a structure enables to issue securities with different characteristics compared to the original assets; in particular, the structure and timing of payments, the associated risk can be different.

Motivations

Legal, regulatory, and accounting rules applicable to securitization transactions differ widely among countries and are subject to the ongoing modification and revision. It is necessary in structuring a securitization transaction to deal with legal, regulatory, and tax rules that may affect the sale and conveyance of the assets from the originator to the SPV. Another important issue relates to the legal framework governing the creation, maintenance, and operation of special purposes vehicles. Finally, depending on the originator's objectives, the balance sheet effects and accounting treatment and consequences of a particular securitization are essential and will frequently influence the ultimate structure of the transaction. In particular, the question of regulatory capital, or in other words, the amount of provisions to be put aside by financial institutions to be authorized by the regulators to have an activity, is essential and has a huge impact on the structure of transactions, as securitization can be used for capital relief to reduce regulatory capital allocations. In the case of insurance-linked securitization, things can be even more complex.

Advantages and Limitations

Securitization offers several advantages to the originator. Among them, one can mention the transfer of risk, the reduction in the asset-liability mismatch and lower capital requirements by removing risk from the balance sheet (improvement of various financial ratios, more efficient use of capital, and compliance with capital standards). It is also a way to lock-in profits by cashing some money today and removing the uncertainty associated with the future cash flows. It can appear as a lower cost source of financing. Obviously, such a process is not for everyone since it is very costly: securitizations are expensive and take time. The more complicated and unusual the transaction is, the more expensive and time consuming it will be. There is also a critical mass to achieve. Only large originators or pools of originators can think of

securitization as a cost-effective way of transferring risks.

As far as investors are concerned, ABS offer an opportunity to invest in a specific pool of assets, with a high credit quality and a relatively large rate of return. This can enhance the diversification of their existing portfolios. There are, however, some risks associated with these financial products: liquidity risk, credit risk, event risk, and prepayment risk appear to be the main sources of uncertainties to which the investors are exposed when buying these products.

Globally, many public, social, and economic benefits can result from securitization. For instance, the existence of a liquid and efficient secondary securitization market increases the availability and reduces the cost of financing for the primary market lenders. It can also reduce geographical and regional disparities in the availability and cost of borrowing by linking local credit activities to global capital markets. Also, securitization can be used as a way to improve capital allocation and reduce risks to individual institutions and systemic risks within the financial system.

General Structure and Key Agents Involved in a Securitization

A typical securitization begins with one (or several) originator having some assets in its book that it wants to divest. The securitization process itself requires several steps, as illustrated in Figure 1. Various agents are involved at different stages of any securitization process.

Issuer and Investors

Even if ABS have been issued on a basis of a large variety of different underlying risks, their overall structure is rather generic. Everything starts with an originator. It initiates the contracts that will be securitized at the end. In other words, the originator provides a product to a customer, who agrees to make a series of payment over a certain period of time. The present value of these payments (capital and interests) constitutes an asset of the originator. Instead of keeping it in its balance sheet, the originator is now able to move it off balance sheet through the securitization process.

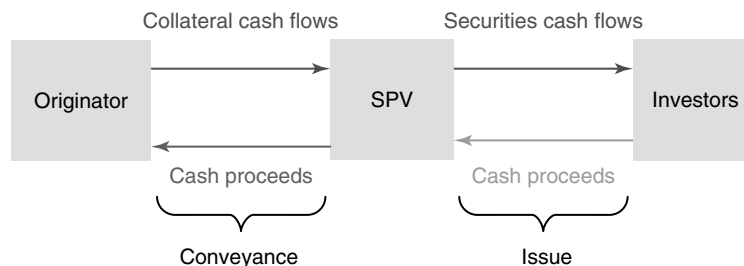

Figure 1 General structure of a securitization process

Special Purpose Vehicle (SPV)

More practically, to issue these new securities, a special purpose vehicle (SPV) is created. This is a passive financial entity, bankruptcy remote, that exists for the sole purpose of purchasing and housing the assets from the originator and issuing securities using the assets as *collateral*. The collateral consists of assets provided to secure an obligation. The name of the securities itself comes from the nature of the collateral: as already mentioned, when the assets are mortgage loans, the securities are collateralized or backed by mortgage loans and so are called *MBS*. When it is a general asset that backs the securities, they are called *ABS*.

Once the assets have been transferred from the originator to the SPV, a process called *conveyance*, the SPV is responsible for managing the collateral (asset) and administrating its different cash flows. It is also responsible for designing the securities to be issued. Since the management of the cash flows is passive and tax-free, the whole cash flows are transferred to the investors. Note that, in general, the conveyance of assets from the originator to the SPV has to be conducted in a manner that results in a *true sale* (i.e., legal isolation), in order to remove the assets from the bankruptcy or insolvency of the originator. In particular, if the originator was to become bankrupt or insolvent, a trustee would not be able to reach the transferred assets to satisfy claims of creditors of the originator.

In summary, after the transfer of the collateral asset to the SPV, the latter issues securities to investors, who, in exchange, pay some money to the SPV in order to buy the securities. Then, the SPV pays all the proceeds from the securities issue to the originator, while the latter will pay the different cash

flows coming from the asset during its life to the SPV so that they can be transferred to the investors.

Cash and Synthetic Structures

In the securitization process described here, the collateral is made of assets from the originator's balance sheet. Some more sophisticated securitization processes also exist without this particular feature, especially in credit risk securitization. The issued securities are usually called *synthetic* (versus cash) since the collateral is recreated synthetically.

A standard example is the (cash) collateralized debt obligations (CDOs), based upon a collateral that is a pool of assets, usually comprising loans and debt instruments (but generally nonmortgage assets). The collateral pool can be made of various assets: investment-grade bonds, high-yield bonds, sovereign debt, bank loans, or even tranches of other CDOs. More precisely, a CDO consists of the issue of several notes, also called *tranches*, having different characteristics (maturity, seniority, etc.). The credit risk of the collateral is borne by the investors of the CDO, but the exposure is different according to the tranche. However, CDOs can also be synthetic (funded or unfunded). In this case, the underlying risk is the credit risk associated with a portfolio of credit default swaps signed by the originator and the SPV. In the funded case, the collateral is constituted by the purchase by the SPV of high credit quality financial instruments such as T-bonds with the initial proceeds from the investors. In the unfunded case, there is no collateral as such and the CDO is therefore similar to a swap contract.

There is an important difference between the cash and synthetic structures coming from the motivation behind the securitization itself: in a standard (cash) securitization, the originator is really at the origins of

the transaction, with the idea of removing some assets and risks from its balance sheet and using the capital in an optimal way. In a synthetic case, the motivations may come more naturally from the investors' side, and the securitization is an answer to the demand for specific products.

Agents Involved before the Transaction

Before the transaction, in addition to the advisor, typically an investment bank designing the overall transaction, and the originator, many other types of agents take part in the structuring of the transaction.

Advisors and Modeling Firms. In a standard securitization process, the originator works with an advisor, typically an investment bank. The advisor is here to design the transaction in its every aspect, even the underwriting. It cannot, however, retain any risk. Its role is that of a pure intermediary, making the overall process feasible. This comes at a cost, the fees being typically 1% of the notional amount of the transaction.

In some cases, especially when the underlying risks are not standard (this is usually the case for insurance-linked risks such as natural catastrophe or life), a modeling firm is called upon to help with the pooling of the risk to be securitized and the valuation of those risks.

Rating Agencies. The risk of any transaction has to be assessed before it can go through. Rating agencies are firms specialized in the risk assessment. The largest are Moodys, Standard and Poors, and Fitch Ratings. Their role is to provide not only an independent, timely, and prospective opinion on the credit worthiness but also the structural integrity and other attributes of the transaction (and also, more generally, an entity or even a government).

As to achieve the desired credit risk profile for the securities, depending upon the nature of the transaction and the assets involved, the asset pool may need to be supported by some types of credit support, called *credit enhancement*. Credit enhancement mechanisms can take various forms, both from external parties and within the structure of the deal. Internal credit enhancement mechanisms are a form of self-insurance, whereas external credit enhancement mechanisms are third party-guarantees and typically involve the participation of a bond insurer or monoline.

Before the issue, rating agencies have to give an assessment of the risk taken by the investor when buying this particular product, that is, risk of not only losing their investment due to a credit event but also any triggering event underlying the transaction (natural catastrophe in the case of a cat-bond, for instance). Once issued, the rating agencies usually (but not always) monitor the performance of the transaction and adjust the rating accordingly. Ratings are assigned and reviewed by a committee process. The rating will be based upon the structure of the transaction, the quality of the various parties, and the risks underlying the new securities. Obviously, this process involves the knowledge of the models available for these particular risks. Rating agencies may therefore work closely with modeling firms when the underlying is not standard. Various credit enhancement strategies can be used to improve the credit quality of a securitization. The rating system generates many problems as revealed by the credit crisis of 2007–2008. In particular, the use of the same rating system for entities and transactions leads to a confusion among investors. While an AAA entity represents a default risk-free entity (this is the case for the G7 countries), an AAA transaction (or tranche) is not exempt from risk. The rating of a structure should also include some other forms of risks (liquidity or market value risks, for instance, which are very important especially for highly sophisticated structures).

Lawyers

The next step before receiving the approval from the regulatory bodies is to write the legal agreement related to the deal. Even if most advisors have an internal legal department, most of them use an independent law firm to write down the contract, as to avoid any responsibility from the legal point of view. The task of these law firms can be very tricky as it requires the knowledge of various legal frameworks depending on the country, or even the state in the United States.

Regulatory Authorities

Finally, any transaction, before going to the financial markets, has to be approved by the regulatory authority of the relevant country or even the relevant state in the United States. In the United Kingdom, it is the

role of the Financial Services Authority (FSA) and in the United States that of the Securities and Exchange Commission (SEC). Both are independent nondepartmental public bodies regulating the financial services.

Insurance-linked Securitization

The convergence of insurance with the capital markets has not only opened up an alternative channel for insurers to transfer risk, raise capital, and optimize their regulatory reserves but also offered institutions a source of potentially liquid and uncorrelated investment exposure. One of the financial instruments allowing for the cession of insurance-related risks to the capital markets is called *insurance-linked securities (ILS)* [2]. Growth in the ILS market has been steady over the past decade, with a number of different structures, risk layers, and trigger types being introduced. When discussing ILS, one needs to take into account the different structural features for high-frequency–low-severity *versus* low-frequency–high-severity transactions in the nonlife sector, or for

regulatory capital, longevity, and extreme mortality trades in the life sector. Motivations also differ according to the structure and the cedant/insured. Catastrophic risk is not only concerned by the securitization process. In theory, any insurance risk, on which policies can be written, can be subject to securitization, and in particular, life insurance risk.

ABS Indices

Asset back securities (ABS) are financial debt securities based on a pool of underlying assets or collateral assets. When the assets are backed by mortgages, they are called *mortgage backed securities* (MBS). ABSs are backed by nonmortgage assets. This includes auto loans, credit card receivables, home equity loans, student loans, and so on. Owing to government guarantees, MBS typically entail no credit risk. However, ABSs generally lack such guarantees, so they entail credit risk. It might be for this reason that ABS backed by subprime mortgages are still called *ABS*, or more explicitly, *subprime residential mortgage-backed security* (RMBS) instead of MBS.

The basic building blocks of credit derivatives are credit default swaps (CDS). It was the standardization of the settlement terms and conditions of the corporate CDS contracts by International Swaps and Derivatives Association (ISDA) in early 1990s that allowed the corporate CDS market to grow and evolve quickly. The credit risk in subprime RMBS differs in fundamental ways from credit risk in corporate bonds. ISDA published its first pay-as-you-go (PAUG) CDS documentation for RMBS in June 2005, and followed up with amended versions in April 2006 and November 2006. This ISDA documentation standardization for PAUG CDS on subprime RMBS helped create a synthetic CDS market on the subprime RMBS bonds. In late 2005, 15 security firms, representing major brokers and dealers, along with an index company CDS Index Co. and a data provider, Mark-It Partner came up with the ABS CDS benchmark index, ABX.HE, for subprime RMBS, and the trading of ABX started on January 19, 2006. The index is supposed to roll every six months with newly issued subprime RMBS bonds as collateral assets. Owing to the subprime crisis and a lack of newly issued subprime RMBS bonds, we have only four series of ABX indices up to now; they are simply called *ABX* 2006-1, *ABX* 2006-2, *ABX* 2007-1, and *ABX* 2007-2 based on the vintage year of underlying subprime RMBS bonds.

Tranched ABX or TABX is the benchmark index tranche product based on ABX. Owing to the relatively small number of collateral ABS bonds of each vintage ABX index, we use the underlying ABS bonds of two conjacent ABX indices as collateral assets for the TABX. Shortly after the introduction

of TABX, the subprime crisis emerged. In practice, TABX has never been liquidly traded. However, there are a large number of issuances of bespoke ABS collateralized debt obligations (CDOs) with non-ABX bonds as collateral assets.

We simply present the contract parts of the ABX and TABX and briefly discuss the modeling of TABX.

ABX

ABX.HE indices are CDS benchmark index for a standard basket of subprime home equity ABS bonds. For each vintage ABX.HE, we have five indices based upon the rating of reference ABS bonds: AAA, AA, A, BBB and BBB— by both Moody's and S&P. The selection of the included bonds is rule-based according to the deal size (at least 500 millions) of the subprime home equity ABS shelf program with a limit from the same loan originator (four deals) and from the same master servicer (to six deals), and the weighted average life (4–6 years from the issuance for other ratings except AAA, and more than 5 years for AAA). Each vintage ABX.HE has 20 underlying collateral bonds, and a new series of index is supposed to be issued every six months.

As stated early, ABX is a CDS spread index whose premium leg or fixed leg is based on two parts: up-front payment in terms of percentage and a running payment in terms of a spread in basis point. This running spread is called a *fixed rate*, which is determined at the beginning so that the initial quote for the index is 100 or we do not need to pay any up-front premium if you buy protection or short the index. The following shows the market quote for ABX on November 28, 2009. Owing to the subprime crisis, most of the current “price” is very low. This implies that we need to pay a very high up-front payment to buy protection. For example, if we want to buy default protection on 2006-01 BBB—, we need to pay $(100 - 5 \cdot 16/32)\% = 94.5\%$ up-front premium based on the notional amount and 267 bps (basis points) running spread per annum, but paid monthly, on the basis of the outstanding notional amount. The outstanding notional amount declines over time on the basis of the reference obligations amortization.

The loss leg includes interest shortfall, write-down, principal shortfall adjusted by interest rate shortfall reimbursement, principal shortfall reimbursement, and write-down reimbursement. The protection buyer receives any interest shortfall, but the

total amount is capped at a fixed rate. A credit event is defined as principal shortfall and write-down according to the 2005 ISDA PAUG template definition.

For example, if any one of the 20 referenced ABS bonds incurs a write-down of 1% in the amount of its current principal balance, and the referenced bond current factor is 70%, then the protection buyer of 100 millions receives the following payment:

$$\begin{aligned} & \text{Notional amount} \times \text{current factor} \times \text{weighting} \\ & \times \text{loss rate} = 100 \text{ millions} \times 0.7 \times 0.05 \\ & \times 0.1 = 35\,000 \end{aligned} \quad (1)$$

After this credit event, the notional amount based on which that fixed rate is paid would be reduced by \$35 000 until the earlier of the next credit event or scheduled termination. ABX has been actively traded since its inception on a daily basis. Table 1 provides a market quote for ABX on Nov 28, 2008.

TABX

TABX was introduced in February 2007 just before the subprime crisis emerged. TABX tranches reference a portfolio of 40 names from underlying bonds from 06-2 and 07-1 ABX.HE series and 07-1 and 07-2 ABX.HE series of a similar rating. Only two tranche baskets were traded initially: BBB and BBB−. The attachment and detachment points for the 06-2 and 07-1 portfolio and the fixed running spreads for all tranches are given in Table 2.

The tranche protection buyer receives protection against the write-downs and principal shortfalls on the reference ABS bonds. No interest shortfalls are

covered by the tranche protection. On the fixed side, all tranches have a specified or fixed running spreads in bps as given in Table 1, and are traded on price up front. Fixed running spreads are capped on roll date at 500 bps. The subordination level is the initial subordination notional amount less write-downs, principal shortfalls, and amortization. Therefore, the detachment and attachment points of the tranche can change over each period depending on the loss evolution and amortization. We could think of TABX, or, broadly speaking, of ABS CDOs as CDOs with changing subordination levels.

Modeling of ABX and TABX

The TABX market was a short-lived one. It was introduced in February 2007. Shortly after its introduction, we observed the first crash of the ABX indices. But there were billions of dollars of ABS CDOs structured and issued by Wall Street firms without ABX index bonds as collateral assets. There is no market consensus with respect to the ABS CDO valuation. Some practitioners tried to adapt the Gaussian copula model for ABS CDOs, which were hard to interpret since the results depended critically on the prepayment assumptions for the underlying subprime loans.

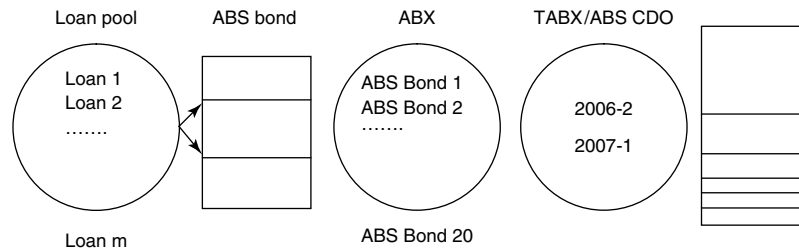

Figure 1 shows the whole securities involved in the TABX or ABS CDOs. The first layer of collateral assets for ABS bonds consists of individual mortgage loans underlying the ABS bonds. Each ABS bond takes about 5000–10 000 individual mortgage loans as collateral assets. Then ABX takes 20 ABS bonds as its underlying assets. The TABX takes 40 ABS bonds as collateral assets and goes through another tranche. The TABX is thus more like a CDO squared transaction. In the market, there is no consensus with

Table 1 Market quote for ABX, November 28, 2008

Series	Fixing rate	Rating	Quote	Series	Fixed rate	Rating	Quote
07-2	76	AAA	33-24/36-24	06-2	11	AAA	46-00/49-00
07-2	192	AA	6.00/8.00	06-2	17	AA	11-00/14-00

06-2 and 07-1	BBB-	40	100	72

**Figure 1** An overview of subprime RMBS products

respect to the CDO squared transaction even though attempts have been made to tackle this problem. One example is the approach in [1] in which the authors use a mixed Gaussian copula function along with the mapping of loss distributions. But this is only for corporate credits that have one risk or “decrement”. For subprime loans, each loan is subject to two decrements: default and prepayment.

We believe the only approach to capture all features and complexities of the TABX or ABS CDOs is a bottom-up approach. In this approach, we model the fundamental driving factors for the mortgage loan pool: prepayment and default. We then generate the cash flows for the ABS bonds using the waterfall structure for each collateral ABS bond (like a cash-flow CDO tranche). This can be accomplished by running Intex. These cash flows include the write-downs, principal, interest rate, and coupon cap shortfalls. We can then aggregate the cash flows for the whole underlying pool of the TABX. The TABX tranche can then be assessed by the aggregate cash flows for the collateral pool. The

dynamics and correlation have been introduced since there are common driving factors for prepayment and default, such as the home price appreciation (HPA) index. All other features are incorporated since we use the waterfall structure for each ABS bond. Calibration of the model to the observed ABX prices can be achieved if we use a few parameters for the prepayment and default curves.

Modigliani–Miller Theorem

The Modigliani–Miller theorem states that the value of a firm is invariant with respect to its leverage policy in an arbitrage-free market when there is no corporate income tax and no bankruptcy cost. Modigliani and Miller (M–M) [10] proved this “invariance” result using, for the first time, a “no-arbitrage” condition.

To present the M–M theorem, we consider a simple levered firm in which there are two basic claimants on the firm’s income:

- *debt holders*, whose security allows them to claim the coupon C at each time t as long as default is not declared;
- *equity holders* (the owners of the firm), whose security allows them, once debt holders have been paid, to claim the *residual cash flow* (if positive) as dividends.

Debt holders are paid *before* equity holders, but their claim does not allow them to receive more than the coupon, no matter what the net result is. On the contrary, dividends received by equity holders may be very high when the net result is very high but can also be very low (and even null) when the net result is very low. Equity holders are frequently called the *residual claimant* since they own the *residual income* (i.e., the net result) of the firm, that is, what remains when employees, debt holders, and government have been paid.

Let E^l and B be the market value of equity and debt, respectively, of a given firm at some point in time. To become the owner of this (levered) firm, an investor must buy not only the equity E^l but also the debt of the firm, so that the total payment is equal to $V^l = E^l + B$, where V^l is called the *value of the firm*. It is thus tempting to think that if we increase B , the value of the firm V^l will also increase. Finding the conditions under which debt affects the value of the firm is the central question of M–M analysis: given a *fixed* investment policy, what are the condition(s) under which debt does not affect the value of the firm?

Basic Statement of the Theorem

Consider a firm that has invested in some productive asset, which allows it to generate an operating income (i.e., the earning before interests and taxes (EBIT)) X_t at each time t . Roughly speaking, X_t is equal to the value of the sales minus production costs. When positive, X_t is used to pay debt holders (coupon), government (tax), and equity holders (dividends).

Unlevered Firm

In this case, the value of the firm at time t is denoted by v_t , and is simply equal to the net result, that is,

$$v_t = X_t(1 - T_a) \quad (1)$$

where T_a is the corporate tax income.

Let C be the coupon of the corporate debt and T be the maturity of the debt. In what follows, we not only consider the case of a *perpetual debt* so that T is infinite but we also assume that each firm distributes all the residual income (or cash flow) as dividends to equity holders. This thus implies that the firm does not have any cash reserve that it can use when the EBIT is not enough to pay the coupon C . Let v_t^l be the value of the levered firm at a given time t . We now compute v_t^l under various scenarios.

Levered Firm—No Default Risk

We say that a perpetual corporate debt is *risk-free* if the coupon C is paid at each time t to debt holders with probability one. Since the debt is risk-free, the net result $(X_t - C)(1 - T_a)$ is positive with probability one.^a The value of the levered firm at time t is thus equal to

$$v_t^l = C + (X_t - C)(1 - T_a) = X_t(1 - T_a) + T_a C \quad (2)$$

$$= v_t + T_a C \quad (3)$$

The value of the levered firm is equal to the value of the unlevered firm v_t , plus the value of the tax-shield $T_a C$, which comes from the fact that interest expenses are tax-deductible. In the particular case in which $T_a = 0$, we thus have the following equality:

$$v_t^l = v_t = X_t \quad (4)$$

When there is no corporate income tax, the value of the levered firm (at time t) is equal to the value of the unlevered one (at time t), that is, the value of the firm is invariant with respect to C as long as the coupon implies no default risk. This is the M–M theorem without default risk.

Levered Firm—Default Risk

We say that the corporate bond is risky if there is a positive probability that the coupon will not be paid to debt holders at some time t . Since all the residual income is distributed to equity holders as dividends, there are no available retained earnings so that default is declared at the first time for which $X_t < C$. Note importantly that in a default^b situation

- debt holders have an unconditional right to be paid before equity holders;
- the firm is not subject to corporate taxation;
- due to *limited liability* of equity holders, debt holders cannot force them to pay the difference $C - X_t$; and
- the bankruptcy cost (i.e., lawyer cost, administrative costs, etc.) is a fraction γ of X_t .

It follows thus that

$$v_t^l = \min\{X_t, C\}(1 - \gamma \mathbf{1}_{X_t < C}) + \max\{(X_t - C)(1 - T_a \mathbf{1}_{X_t \geq C}); 0\} \quad (5)$$

where $\mathbf{1}_{X_t \geq C}$ and $\mathbf{1}_{X_t < C}$ are indicator functions.^c When there is no default, the value of the firm is given by equation (3). However, when there is default, the value of the firm is equal to $X_t(1 - \gamma)$. In the particular case in which $\gamma = 0$ and $T_a = 0$, it follows that

$$v_t^l = \min\{X_t, C\} + \max\{(X_t - C); 0\} = v_t = X_t \quad (6)$$

When there is no bankruptcy cost and no corporate income tax, the value of the levered firm is equal to the value of the unlevered one, that is, the value of the firm is invariant with respect to the coupon. This is the M–M theorem with default risk.

Classical Presentation

In their original work, Modigliani and Miller [10] make the following assumptions.^d

1. Capital markets are perfectly competitive.
2. Individuals and firms can borrow and lend at the risk-free rate r .
3. All firms are assumed to be in the same *class risk*.

Assumption 1 implies that market investors have full (and symmetric) information concerning the return of the firm, that there are no transaction costs, and that there are no restriction on asset trade, that is, long and short positions are possible. Assumption 2 means that when firms or households borrow, they are not subject to default risk so that they can borrow at the risk-free rate. Assumption 3 means that the stream of EBIT is the same for all firms in the same class risk; if two firms, one levered and one unlevered, belong to the same class risk, then, they differ only with respect to leverage.

In their original work, Modigliani and Miller [10] consider a discrete-time model in which the family of random variable $\{X_t\}_{t \geq 1}$ is identically and independently distributed. Let $\mathbb{E}(X_t) = \bar{X}$ be the expectation of X_t under the probability measure $\mathbb{P}$. In the present framework, the corporate debt is riskless if $\mathbb{P}(X_t > C) = 1$.

Cost of Capital and Valuation Principle

In M–M [10], the valuation principle is fairly simple: the present value of a stream of *risky* cash flow is equal to the *expected* sum over time of the *discounted* value of the cash flow. The expectation is taken under the probability measure $\mathbb{P}$, and the discount factor, also called *risk adjusted rate of return* or, more simply, the *cost of capital* incorporates a risk premium. Since, in general, investors are risk averse, the riskier the cash flow, the higher is the cost of capital. Let r be the cost of capital of a riskless cash flow and $k_u > r$ be the cost of capital of a risky cash flow.

Using the above principle, the value of the unlevered firm is equal to the present value of the flow of v_t , that is,

$$V = E = \mathbb{E} \sum_{t=1}^{\infty} \frac{v_t}{(1 + k_u)^t} = \frac{\bar{X}(1 - T_a)}{k_u} \quad (7)$$

where V denotes the value of the unlevered firm, which is also equal to the value of equity E . To determine the value of the levered firm now, we have to compute the expected discounted value of the flow of v_t^l . Using equation (3), we just have to compute the value of the stream of tax shield. By assumption, the corporate debt is a perpetual risk-free one, so that the relevant cost of capital for the tax shield is r . It thus follows that

$$\begin{aligned} V^l &= \mathbb{E} \sum_{t=1}^{\infty} \frac{X_t(1 - T_a)}{(1 + k_u)^t} + \sum_{t=1}^{\infty} \frac{T_a C}{(1 + r)^t} \\ &= V + T_a \frac{C}{r} = V + T_a B \end{aligned} \quad (8)$$

where $B = \frac{C}{r}$ is the value of the perpetual corporate risk-free debt, and $T_a B$ the value of the perpetual tax shield. The value of the levered firm is thus equal to the value of the unlevered firm plus the value of the tax shield. We can now state the famous invariance result when $T_a = 0$. Let $\frac{B}{E^l}$ be the *debt–equity ratio* where $E^l = V^l - B$ is the value of equity of the levered firm.

Modigliani–Miller Theorem with Risk-free Debt

In addition to the above assumptions, suppose that there is no arbitrage opportunity and no corporate income tax (i.e., $T_a = 0$); then, $V = V^l$, that is, the value of the firm is invariant with respect to the debt–equity ratio.

This result implies that when there are no taxes and no default risk, the value of the firm is *invariant* with respect to the “financing policy”, which means that issuing only equity or issuing a mix of debt and equity does not affect the value of the firm. Fundamentally, the value of the firm is determined by the stream of EBIT, that is, by the investment policy; debt affects only the *split* of the value of the firm between debt holders and equity holders. As a consequence, different debt–equity ratios lead to different splits of the total value but have no impact on this total value.

From a mathematical point of view, the proof is trivial, since when $T_a = 0$, we immediately get that $V = V^l$. Actually, Modigliani and Miller became very famous not only for the result *per se*, but also because they offered, for the first time, a *no-arbitrage*

principle^c for security valuation: they showed that if $V^l > V$ when $T_a = 0$, then, there is an arbitrage opportunity.

While the proof is rather simple, it highlights their assumptions. Consider two firms that are in the same class risk. The first is unlevered while the second is levered. Since $T_a = 0$, the value of equity of the levered firm is equal to $E^l = V - C/r$ while the value of equity of the unlevered firm is $V = E$. Consider now an equity holder who owns $\kappa\%$ of the shares of the levered firm. At each time t , his/her claim D_t (i.e., dividend) is equal to

$$D_t = \kappa(X_t - C) \quad (9)$$

Suppose now that he/she sells his/her part of the levered firm for an amount κE^l and borrows an amount equal to $\kappa(C/r)$. With that money, he/she buys a fraction $\frac{\kappa(E^l + (C/r))}{V}$ of the shares of the unlevered firm. Actually, the equity holder borrows an amount $\kappa C/r$ to *replicate* the leverage of the firm, and this has been called a *homemade leverage*. Note importantly that by assumption 2, the investor borrows at the risk-free rate. He/she thus holds a portfolio in which he/she will not only perceive the dividends (in proportion of his/her part) of the unlevered firm at each time t but will also have to pay the interest expense equal to κC . The return of his/her portfolio is thus equal to $Y_t = \frac{\kappa(E^l + C/r)}{V} X_t - \kappa C$. By definition, $V^l = E^l + B$ so that Y_t is equal at each time t to

$$Y_t = \kappa \left(\frac{V^l}{V} X_t - C \right) \quad t \geq 1 \quad (10)$$

Since $V^l > V$ by assumption, it thus follows that $Y_t > D_t$ with probability one, which is an arbitrage opportunity. If we rule out such an arbitrage opportunity, then, $V^l = V$.

As Duffie [2] remarks in his review on M–M theorem, the result follows because equity holders can undertake the same financial transaction as the firm in exactly the same condition. If an equity holder is considered as defaultable so that he/she must borrow at a rate higher than the risk-free rate, then, he/she cannot offset the financial decision of the firm at the same price.

The Cost of Equity and the Debt–equity Ratio

From equation (7), when $T_a = 0$, the cost of capital $k_u = \bar{X}/E$ is the (expected) rate of return on equity. When the firm is levered, with $T_a = 0$, the (expected) rate of return of the levered firm k_e that we call *cost of equity* is equal to

$$k_e = \frac{\bar{X} - C}{E^l} \quad (11)$$

Since the firms are in the same class risk, the mean EBIT $\bar{X}$ of the two firms are equal. As a consequence, by writing equation (11) as $\bar{X} = E^l k_e + rB$ (recall that $C = rB$), since $\bar{X} = k_u E$, it thus follows that

$$E^l k_e + rB = k_u E \quad (12)$$

The M–M theorem implies that $V = V^l \equiv E^l + B$. Since $V = E$, from equation (12), we easily obtain that

$$k_e = k_u + (k_u - r) \frac{B}{E^l} \quad (13)$$

Equation (13) means that *ceteris paribus*, the higher the debt–equity ratio, the higher is the cost of equity of the levered firm. More precisely, the cost of equity is a *linear* increasing function of the debt–equity ratio, and is sometimes thought of as a pricing formula where $(k_u - r) \frac{B}{E^l}$ is the premium for the *financial risk*. See [14] for a presentation of the various existing formulas of the cost of capital.

Contrast with Empirical Evidence

In contrast to the M–M theorem, the value of firms is actually influenced by their capital structure: the debt–equity ratio affects the value of the firm. To explain the observed debt–equity ratio, a large part of the recent theory of capital structure has been to explore the role of the conflicts, inexistent in the M–M analysis, that arise among managers, equity holders, and debt holders. Informational asymmetries play an important role. The article of Harris and Raviv [5] and the books of Milgrom [9] or Hillier *et al.* [7] contain a very readable presentation of many aspects of the recent theory of capital structure.

Modern Presentation

We now present the M–M theorem in a continuous-time setting assuming that markets are arbitrage free

and complete^f so that there exists a *unique pricing measure* (also called risk-neutral measure) denoted by $\mathbb{Q}$. More precisely, we assume that under the unique risk-neutral measure $\mathbb{Q}$, the stochastic process $X = (X_t)_{t \geq 0}$ is given by

$$X_t = x e^{(\mu - 0.5\sigma^2)t + \sigma W_t} \iff \frac{dX_t}{X_t} = \mu dt + \sigma dW_t \quad (14)$$

where μ is the risk-neutral drift, σ is the volatility, W_t is a standard Brownian motion under $\mathbb{Q}$, and x is the value of the EBIT at time $t = 0$. In what follows, the expectation is taken under the pricing measure $\mathbb{Q}$.

Valuation Principle

In the “modern” approach, one also values a stream of risky cash flow as the *expected* sum over time of the *discounted* value of the cash flow. The discount rate is now always equal to the risk-free rate r , whether the cash flow is risky or not, and, to prevent arbitrage,^g the pricing measure $\mathbb{Q}$ is such that the *overall expected rate of return* of the unlevered equity, that is, expected capital gain plus dividend yield, is equal to the risk-free rate r .

The value of the unlevered firm seen from $t = 0$, which is also the value of equity, is equal to the expected sum of discounted v_t (see equation 1) over time, that is

$$\begin{aligned} V(x) \equiv V &= \mathbb{E} \int_0^\infty e^{-rt} v_t dt \\ &= \mathbb{E} \int_0^\infty e^{-rt} X_t (1 - T_a) dt \end{aligned} \quad (15)$$

$$= \frac{x(1 - T_a)}{r - \mu} \quad \mu < r \quad (16)$$

Seen from a given time $t > 0$, the value of the unlevered firm (or equity) is equal to

$$V_t = \frac{X_t(1 - T_a)}{r - \mu} \quad (17)$$

We assume, as previously, that equity is a *traded asset*, whose price is V_t at time t . Since all the residual cash flow is distributed to equity holders as dividends, the dividend yield is equal to $\frac{X_t(1 - T_a)}{V_t} =$

$r - \mu$, which means that $\mu < r$. As a consequence, the overall expected rate of return from holding the equity of the unlevered firm is equal to r , that is, the expected capital gain μ plus the dividend yield $r - \mu$.

Default Risk

The existence of default risk complicates the analysis of the preceding section, since the flow of v_t^l may be stopped at a random time τ . Moreover, if default occurs at time τ , a fraction γV is lost due to bankruptcy costs. As a consequence, the value of the levered firm is equal to V plus the value of the tax-shield TS minus the value of the bankruptcy costs BC . The value of the levered firm V^l at time $t = 0$ is thus equal to

$$V^l = V + TS - BC \quad (18)$$

To compute the value (at time $t = 0$) of the tax-shield TS and of the bankruptcy costs BC , we now have to specify the default declaration mechanism. It is assumed that default is triggered at the first time $t > 0$ for which $V_t \leq V_B$, with $V_B < C/r$. Let τ denote the default time. Since (almost all) the sample paths of the stochastic process V_t are continuous, default occurs at the first time for which $V_t = V_B$. It follows that

$$\tau = \inf\{t \in \mathbb{R}^+ : V_t = V_B\} \quad (19)$$

It can be shown^h that, for a perpetual corporate debt, the risk-neutral default probability is equal to

$$\left(\frac{V_B}{V}\right)^{2(\mu - 0.5\sigma^2)/\sigma^2} \quad (20)$$

To determine TS and BC , we follow [3] and first compute the present value of a contingent claim that pays €1 if the firm defaults. Seen from $t = 0$, if the default time τ were to be known, its value would be equal to $e^{-r\tau}$. Since $\tau > 0$ is not known, the value of such a contingent claim is equal to its expected value. It can be shownⁱ that

$$\lim_{T \rightarrow \infty} \mathbb{E}(e^{-r\tau} \mathbf{1}_{\tau < T}) = \left(\frac{V_B}{V}\right)^\xi \quad (21)$$

where $\xi = \frac{1}{\sigma^2}[(\mu - 0.5\sigma^2) + \sqrt{(\mu - 0.5\sigma^2)^2 + 2r\sigma^2}] > 0$, and $\mathbf{1}_{\tau < T}$ is the indicator function of the event $\tau < T$ (recall that T is the maturity of the debt).

Consider now the value of the bankruptcy costs. Seen from $t = 0$, when default occurs at time $\tau > 0$, their value is $e^{-r\tau} \gamma V_B$ while if default never occurs, their value is zero. Using equation (21), it thus follows that the value of the bankruptcy costs is equal to

$$BC = \lim_{T \rightarrow \infty} \mathbb{E}(\gamma V_B e^{-r\tau} \mathbf{1}_{\tau < T}) = \gamma V_B \left(\frac{V_B}{V}\right)^\xi \quad (22)$$

In the same way, since the tax shield is positive as long as default is not declared, its value is equal to

$$TS = \left(1 - \left(\frac{V_B}{V}\right)^\xi\right) T_a(C/r) \quad (23)$$

The value of the levered firm, defined by equation (18), is thus equal to

$$V^l = V + \left(1 - \left(\frac{V_B}{V}\right)^\xi\right) T_a(C/r) - \left(\frac{V_B}{V}\right)^\xi \gamma V_B \quad (24)$$

Note that when V (or x) tends to infinity, equation (24) reduces to equation (8) since default risk vanishes. When $T_a = 0$ and $\gamma = 0$ in equation (24), it thus follows that $V^l = V$.

Modigliani–Miller theorem with risky debt

Assume that markets are arbitrage free and complete and that there are no corporate income taxes (i.e., $T_a = 0$) and no bankruptcy costs (i.e., $\gamma = 0$). Then $V = V^l$, that is, the value of the firm is invariant with respect to the debt–equity ratio.

Default risk does not invalidate the M–M theorem as long as there are no taxes and no bankruptcy costs. When there are both tax and bankruptcy costs, the debt–equity ratio that maximizes the value of the firm is an optimal trade-off between the value of the tax shield and the value of the bankruptcy costs.^j However, it is assumed not only that there is no cash reserve (due to the particular dividend policy) but also that equity holders can *costlessly* issue new shares to avoid default if they want to do so.

Assume now that some fraction of the net income (when positive) is not distributed to equity holders as

dividends, it goes on a cash reserve that capitalizes at a rate equal to $r - \lambda$. The parameter λ reflects inefficiencies of managerial expenses (agency costs) so that some fraction of the cash can be considered as lost. When there are both issuance and agency costs, it has been shown that the *optimal dividend policy*^k is an optimal trade-off between these two costs.

End Notes

^aThis might not be the case if, for example, equity holders issue new equity to pay $C - X_t$ to bondholders when $X_t < C$.

^bHere, we make no difference between default and liquidation.

^cRecall that the indicator function of an event A is such that $\mathbf{1}_A = 1$ if $\omega \in A$ and 0 otherwise.

^dSee [13] for a lucid discussion of their assumptions.

^eTheir no-arbitrage proof was indeed misunderstood. See [6] and the reply in [11].

^fIn a section entitled Arrow-Debreu Securities, [12] shows the M–M theorem in a (static) complete market setting. For a treatment of the incomplete market case, see [1] or [4].

Multifractals

Since the early work of Mandelbrot on the fluctuations of the cotton price in the early sixties, it is well known that market price variations are poorly described by the standard geometric Brownian motion [14]. Extreme events are more probable than in a Gaussian world and volatility fluctuations are well known to be of an intermittent and correlated nature. As we discuss in this article, multifractal analysis has provided new concepts and tools to analyze market fluctuations and has inspired a particularly elegant family of models that accounts for the main observed empirical properties in a parsimonious way. These models while capturing the “heteroskedastic” nature of return fluctuations, still preserve, in some sense, the nice stability property across timescales of Brownian motion. This sharply contrasts with classical econometric models that can hardly be controlled as the timescale is changed.

Multifractal Scaling

Let $p(t)$ be the price of some asset at time t , $X(t) = \ln[p(t)]$ and $\delta_\ell X(t)$ the log return between times t and $t + \ell$: $\delta_\ell X(t) = X(t + \ell) - X(t)$.^a $X(t)$ will be called a *multifractal process* if, for a range of q , the order q absolute moment of $\delta_\ell X(t)$ behaves as a power law when ℓ varies

$$M(q, \ell) = \mathbb{E} [|\delta_\ell X|^q] \sim C_q \ell^{\zeta(q)}, \quad l \leq T \quad (1)$$

where $\mathbb{E}[\cdot]$ stands for the mathematical expectation, the exponent $\zeta(q)$ is a nonlinear concave function of q and T is a large characteristic timescale referred to as the *integral scale*.

The multifractal nature of market data is illustrated on the S&P 500 index in Figure 1 using traded prices sampled every 10 min. In perfect agreement with equation (1), log–log plots of $M(q, l)$ versus ℓ show linear behavior up to a scale of the order of $T \simeq 1$ year and the so-obtained $\zeta(q)$ spectrum (using linear regression) turns out to be well fitted by a parabolic shape. The S&P 500 future index can thus be considered, at least at this description level, as a multifractal signal. During the last decade, a lot of works have studied various market data within the framework of multifractal scaling analysis: on

FX rates, commodity markets, stock markets, future markets, and emerging markets (see [2] for a review). These studies point to multifractality as a stylized feature of financial time series.

The scaling of return moments as a function of the timescale ℓ is, in fact, intimately related to some self-similarity property of the process $X(t)$. A process $X(t)$ is called *self-similar* of exponent H if it has stationary increments and if $\forall s > 0$,

$$\delta_{s\ell} X(st) \stackrel{\text{Law}}{=} s^H \delta_\ell X(t) \quad (2)$$

This means that the original process and a dilated version of it are statistically undistinguishable. In that case, $M(q, \ell) \sim \ell^{qH}$ and $\zeta(q)$ is a linear function of q . To account for multifractality (i.e., nonlinear $\zeta(q)$), one can replace the deterministic factor s^H by a random one and get the stochastic self-similarity property:

$$\delta_{s\ell} X(st) \stackrel{\text{Law}}{=} W_s \delta_\ell X(t) \quad (3)$$

where $W_s = e^{\omega_s}$ is a positive random variable independent of the process X and which law is log infinitely divisible and only depends on s . From this equation, it is easy to show that $\zeta(q) = \ln \mathbb{E} [e^{-q\omega_s}] / \ln s$. The multifractality *strength* of the process is generally characterized by the curvature of $\zeta(q)$, that is, by the so-called intermittency coefficient $\lambda^2 = -\zeta''(0)$. The simplest nonlinear case is the log-normal model that corresponds to a parabolic $\zeta(q)$ (i.e., ω_s is Gaussian).

Let us point out that the stochastic self-similarity implies (i) that the smaller the ℓ is, the *fatter* the tails of the probability distribution function (PDF) of $\delta_\ell X$ are and (ii) that the covariance function of $\ln |\delta_\ell X|$ is slowly decreasing (up to scale T) as the logarithm of the lag. These two features are indeed observed on most financial data as illustrated on S&P 500 future data in Figures 2 and 3.

Random Cascades Models

Let us first note that, following an idea of Mandelbrot [14], if $\theta(t)$ (referred to as the *trading time*) is a nondecreasing multifractal process satisfying equation (3) and $B(t)$ a Brownian motion that is independent of $\theta(t)$, then the process

$$X(t) = B[\theta(t)] \quad (4)$$

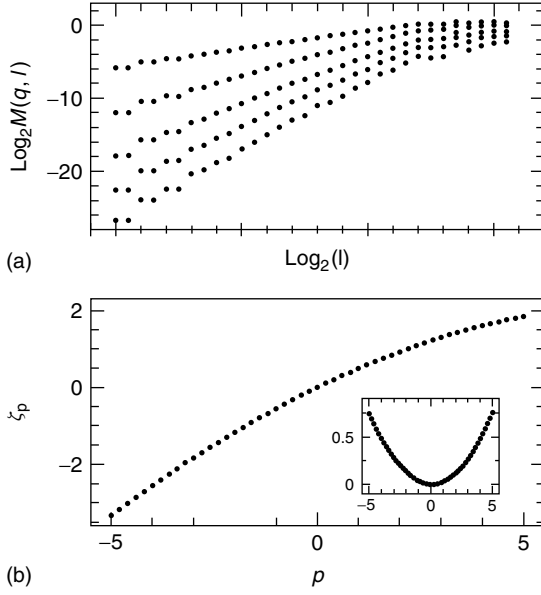

Figure 1 Multifractal Analysis of S&P 500 future index. Traded prices have been sampled every 10 min during the period 1988–1999. (a) Log–log plots of $M(q, l)$ versus l for $q = 1, 2, 3, 4, 5$. The timescales l range from 10 min to 6 years. They display linear behavior up to a scale $T \simeq 1$ year. (b) $\zeta(q)$ spectrum obtained by linear regression of plots on the left. The plot in the inset is the parabolic nonlinear part of $\zeta(q)$

is also multifractal with $\zeta_X(q) = \zeta_\theta(q/2)$. If we write $\theta(t) = \int_0^t d\theta(t)$, the *multifractal random measure* $d\theta(t)$ can be seen as the *instantaneous stochastic volatility*. Consequently, multifractal models of asset returns reduce to multifractal models of volatility measures.

Discrete multiplicative cascades were first introduced in the field of empirical finance by the pioneering work of Calvet *et al.* on exchange rates volatility [15]. Their construction is a direct translation of the self-similarity property (3). In the simplest case, the construction of $\theta(t)$ involves a dyadic tree in a timescale (t, s) half plane. The level n lies at scale $s_n = T2^{-n}$ and has 2^n nodes $\{p_{n,k}\}_{0 \leq k < 2^n}$, which are uniformly distributed on $[0, T]$ leading to a partition made of 2^n intervals $I_{n,k}$ of size s_n . Moreover, i.i.d. (positive) log infinitely divisible random factors $W_{n,k}$ are associated with the nodes $p_{n,k}$. The cascading process starts at the integral scale $s_0 = T$ where a measure is uniformly spread on $[0, T]$: $d\theta_0(t) = dt$. At step $n = 1$, the measure $d\theta_1(t)$ is obtained from

$d\theta_0(t)$ by multiplying its density on the interval $I_{1,0}$ (respectively, $I_{1,1}$) by the corresponding factors $W_{1,0}$ (respectively, $W_{1,1}$). At step n , $d\theta_n(t)$ is obtained by multiplying $d\theta_{n-1}(t)$ on each $I_{n-1,k}$ by $W_{n-1,k}$ leading to the representation

$$d\theta_n(u) = 2^{-n} e^{\sum_{i=1}^n \delta\omega_{i,u_k}} dt \quad (5)$$

where $W_{i,u_k} = e^{\delta\omega_{i,u_k}}$ and u_k corresponds to the integer part of $u2^n$. Finally, one gets $d\theta(t) = \lim_{n \rightarrow +\infty} d\theta_n(t)$.

Grid-bounded cascades, though simple, do not provide a satisfying solution to model volatility fluctuations: (i) they involve an arbitrary fixed scale ratio, (ii) they are not built in a causal way, and (iii) they are not stationary. In their “Poisson multifractal model”, Calvet and Fisher [7] get rid of (ii) and (iii), by basically replacing, for a fixed n , the points $\{p_{n,k}\}_k$ by random Poisson points with intensity $r(s_n) = s_n^{-1}$. Barral and Mandelbrot [5] go one step further (getting rid of (i)), by replacing the points $\{p_{n,k}\}_{n,k}$ and their associated weights $\{W_{n,k}\}_{n,k}$ by a nonhomogeneous spatial compound Poisson process, with the compound law W and the intensity $r(s, t) = s^{-1}$. This construction can be generalized by replacing the compound Poisson process by an arbitrary infinitely divisible random noise $d\omega(t, s)$ in the half plane (t, s) (with density $dt ds/s^2$). Equation (4) is replaced by

$$d\theta_s(t) = e^{\int_{(s', t') \in C_s(t)} d\omega(t', s')} dt \quad (6)$$

where $C_s(t)$ is a cone-like domain (pointing at $(0, t)$ and truncated below scale s). This construction [3] corresponds to the fully continuous generalization of equation (4). The limiting measure $d\theta(t) = \lim_{s \rightarrow 0} d\theta_s(t)$ is shown to be stochastic self-similar, with *exact* scaling ($M(q, l) = C_q l^{\zeta(q)}$, $\forall l \leq T$) and having none of the drawbacks (i)–(iii). Of course, the corresponding $X(t) = B(\theta(t))$ process shares exactly the same properties, it is referred to as a *multifractal random walk (MRW)*.

The “simplest” MRW model corresponds to the case W is log-normal. In that case $d\omega(t', s')$ is a Gaussian white noise, and it can be shown that $\theta(t)$ can be obtained directly by

$$\theta(t) = \lim_{\Delta \rightarrow 0} \int_0^t e^{2\omega_\Delta(u)} du \quad (7)$$

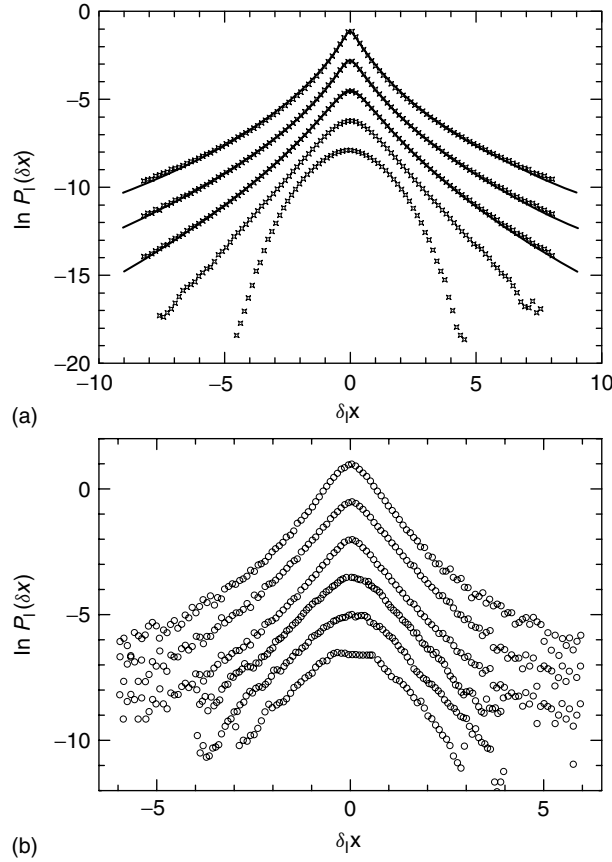

Figure 2 Continuous deformation of increment PDF's $\delta_\ell X$ across scales. Standardized PDF's (in logarithm scale) at large (b) to small (a) scales. Plots have been arbitrarily shifted along the vertical axis to illustrate the tails getting fatter as the scale is going smaller. (b) same S&P 500 data as in Figure 1. The scales range from 10 min to 1 month. (a) MRW Model with $\lambda^2 = 0.03$, $\Delta = 1/16$ and $T = 8192$. The scales range from 16 sampling size to two integral scales. Estimation ($\circ$) made from 500 MRW realizations of 2^{17} sampled points. The solid line corresponds to the prediction from the largest scale using equation (10)

where the *magnitude process* $\omega_\Delta(u)$ is a stationary Gaussian process fully defined by

$$\mathbb{E}[\omega_\Delta(t)] = -\lambda^2 \ln\left(\frac{T}{\Delta}\right) \quad (8)$$

$$R_\Delta(\tau) = \begin{cases} \lambda^2 \left(\ln\left(\frac{T}{\Delta}\right) + 1 - \frac{\tau}{\Delta} \right), & \tau \leq \Delta \\ \lambda^2 \ln\left(\frac{T}{\tau}\right), & \tau \in [\Delta, T] \\ 0, & \tau > T \end{cases} \quad (9)$$

where $R_\Delta(\tau) = \mathbb{Cov}(\omega_\Delta(t), \omega_\Delta(t + \tau))$.

Statistical issues such as parameter estimation remain to be studied (see [18]). Calvet and Fisher [7] introduced a Markov-switching version of their

cascade model that is amenable to maximum likelihood estimation. They were the first to propose a generalized method of moments (GMMs) to estimate the parameters of their model (see also [12, 13] for discrete cascades). The log-normal MRW model is fully defined by three parameters: σ^2 the variance of the Brownian motion, T the integral scale (decorrelation timescale of the volatility), and λ^2 the intermittency factor, which is involved in the nonlinear part of ζ_q (equation (8)). Since, as briefly discussed below, many of statistical moments associated with the MRW model can be analytically computed, GMM can be simply devised and all these parameters can be easily estimated [11]. We observed that for both

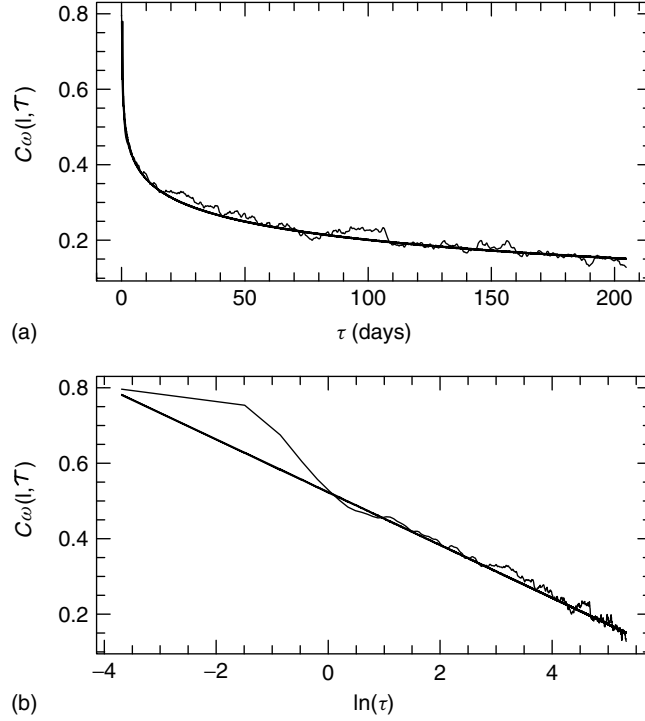

Figure 3 Log-volatility covariance $C_\omega(\ell, \tau)$ of the S&P 500 future. (a) $C_\omega(\ell, \tau)$ versus τ for $\tau = 10$ min. The solid line represents a fit according to the MRW model logarithmic expression. (b) $C_\omega(\ell, \tau)$ versus $\ln(\tau)$. The MRW model predicts a linear behavior that crosses the y-axis at $\ln(\tau) = \ln(T)$

the daily and intraday financial data, the correlation time T is very large (greater than one year) and the parameter λ^2 lies in $[0.02, 0.05]$.

Properties and Risk Forecasting

As far as multifractal properties are concerned, $X(t)$ verifies the exact stochastic self-similarity property as defined by equation (3) and therefore its moments behave exactly as a power law of the timescale ($\ell \leq T$) with a parabolic multifractal spectrum

$$\zeta(q) = q \left(\frac{1}{2} + \lambda^2 \right) - \frac{\lambda^2}{2} q^2 \quad (10)$$

Many other scaling laws can be computed and notably those of “ p -volatility” correlations $C_p(\ell, \tau) \equiv \mathbb{E} [|\delta_\ell X(\tau)|^p |\delta_\ell X(0)|^p]$. In [17], it is shown that

$$C_p(\ell, \tau) \sim K_p^2 \left(\frac{\ell}{T} \right)^{2\zeta_p} \left(\frac{\tau}{T} \right)^{-\lambda^2 p^2} \quad (11)$$

where the constant K_p can be computed analytically. For proofs and details, see [2, 3]. Although they did not explicitly refer to the framework of multifractal analysis, Ding and Granger [9] were the first to observe a nontrivial dependence of $C_p(\ell, \tau)$ as a function of p . Note that when $p \rightarrow 0$, one recovers the logarithmic slowly decreasing of the log-volatility covariance $C_\omega(\ell, \tau)$ as illustrated in Figure 3.

Equation (9) can be directly used to predict volatility. In [7], Calvet and Fisher have already shown that their cascade model provides better volatility forecasts as compared to GARCH(1,1) or Markov-switching GARCH (see also [13]). Bacry and Muzy [2, 4] have shown that linear volatility forecast provided by the MRW model outperforms GARCH(1,1) models.

Actually, the MRW model allows to estimate the full (conditional) return probability density function at all time horizons and scales. Very much like standard Brownian motion that is stable with respect to time aggregation, the self-similarity properties

of the MRW process $X(t)$ allows to control how the return probability law changes when varying the timescale. Indeed, it can be shown that, in a good approximation, when $\lambda^2 \ll 1$, the returns of the MRW process, can be written, in law, as

$$\delta_\ell X(t) \underset{\text{Law}}{\simeq} \epsilon_\ell(t) e^{\Omega_\ell(t)} \quad (12)$$

(see [4] for details and for the precise meaning of the symbol $\simeq$) for all $\ell \leq T$, where ϵ_ℓ is a Gaussian white noise of variance $\sigma^2 \ell$ and the process $\Omega_\ell(t)$ is the *renormalized magnitude*. It is a stationary Gaussian process whose mean and covariance are very similar to equation (7). In Figure 2, we see that, as observed for S&P 500 data, the MRW returns PDF strongly depends on the timescale and evolves from a “quasi-Gaussian” shape at large scales ($\ell \simeq T$) to PDF’s with high kurtosis at small scales. Even if the precise shape of the PDF tails returns is a matter of debate, the most commonly admitted form is a power law with a tail exponent μ within the interval [3, 5] (see, e.g., [6, 10]). The MRW model allowed to point out [1, 16] that this behavior is strongly related to the choice of the asymptotics in the estimation process. The “high-frequency asymptotics” (sampling frequency going to infinity) has to be distinguished from the “long duration asymptotics” (duration of the considered time period going to infinity).

All previous considerations can be extended to conditional laws and can be of practical interest for VaR forecasting. As shown in [2, 4], MRW predictions of VaR at various time horizons can be more reliable than predictions based on a GARCH(1,1) model.

End Notes

^aWe do not address here the modeling of intraday modulation of the data. This modulation can be removed following [8]. We consider that $\delta_\ell X(t)$ is stationary and has zero mean.

Random Matrix Theory

Random matrix theory is the study of matrices with random entries. It has been applied in quantitative finance for the estimation of large covariance matrices which are of interest in portfolio optimization (see **Modern Portfolio Theory; Risk–Return Analysis**). This estimation problem is linked to understanding the properties of *large-dimensional random matrices*.

If daily returns on n days for p different assets are represented as an $n \times p$ matrix X , the sample covariance matrix $\hat{\Sigma}$ is defined as

$$\hat{\Sigma} = \frac{1}{n-1}(X - \bar{X})(X - \bar{X})' \quad (1)$$

where X' is the transpose of X and $\bar{X}$ is a $(n \times p)$ matrix of means, that is, its k th column has constant value equal to the mean of the k th column of X . These matrices are important in practice because they are used to estimate from the data the (unknown) population covariance Σ , when the rows of X , $\{X_i\}_{i=1}^n$ are assumed to be independent identically distributed (i.i.d.) p -dimensional vectors with covariance Σ . When that is the case, $\hat{\Sigma}$ is an unbiased estimator of Σ , that is, $E(\hat{\Sigma}) = \Sigma$.

In the Markowitz portfolio optimization problem (see **Risk–Return Analysis**), optimal weights for different assets are allocated according to a formula involving the covariance Σ of the assets. Since Σ is unknown, it is necessary to estimate it, and the sample covariance matrix is often used as an estimator. Note that for large portfolios, p will be quite large, of order 100 for instance. Also, if looking at daily returns, the number of days, n , used to compute $\hat{\Sigma}$ is often chosen not to exceed a year or two of trading, and is also therefore of order a few 100s (roughly 250 to 500). Hence, in financial practice, it will often be the case that both p and n are “large”.

This is in contrast to the classical theory (see [1]), which is concerned with asymptotics where p is held fixed and n goes to infinity. In this setting of “small p , large n ”, the sample covariance matrix is known to be a good estimator of the population covariance. For instance, the sample eigenvalues can be shown to be close to the population eigenvalues, and similarly for corresponding eigenspaces. Practically, it means that using the sample covariance matrix in the solution of

a Markowitz portfolio optimization problem with a few assets will work “well”, if we observe the assets for a long enough time.

The “large p , large n ” situation is very different and is the one that is studied in random matrix theory. Roughly speaking, what happens in that situation is that, under “reasonable” assumptions detailed later, the eigenvalues of $\hat{\Sigma}$ become inconsistent estimators of the eigenvalues of Σ . Similarly, problems develop with eigenvectors.

The first result in this area was obtained by Marčenko–Pastur [21]. A subcase of the result shown there can, for instance, be interpreted as saying that if the entries of X are i.i.d $\mathcal{N}(0, 1)$, the histogram of eigenvalues of $\hat{\Sigma}$ is asymptotically *nonrandom* (though the matrix itself is random) and moreover its shape can be described. The limiting density of eigenvalues is, if $p/n \rightarrow r \in (0, 1)$,

$$f_r(x) = \frac{1}{2\pi r} \frac{\sqrt{(b-x)(x-a)}}{x} 1_{a \leq x \leq b} \quad (2)$$

In the above equation, $b = (1 + \sqrt{r})^2$ and $a = (1 - \sqrt{r})^2$. The probability distribution with corresponding density is often called the *Marčenko–Pastur law*. It is illustrated in Figure 1. (If $r > 1$, there is also a point mass of mass $(1 - 1/r)$ at 0.)

Several general facts about eigenvalues of random matrices can be observed in Figure 1. First, the sample eigenvalues are more dispersed than the population eigenvalues. Second, the extreme eigenvalues exhibit bias: instead of converging to the population (or “true”) extreme eigenvalues, which in the case above are concentrated at 1, the largest (respectively, smallest) sample eigenvalue is asymptotically at least as large as $b = (1 + \sqrt{r})^2$ (respectively, as small as $a = (1 - \sqrt{r})^2$). Under certain moment conditions on the entries of X , it can actually be shown that the extreme eigenvalues of $\hat{\Sigma}$ converge to b and a . We now turn to a more precise presentation of the results we have hinted at.

Eigenvalues of Sample Covariance Matrices

Two types of results are available for eigenvalues of sample covariance matrices: results dealing with the behavior of the “bulk” of eigenvalues and “edge” results, which deal with extreme (maximal or minimal) eigenvalues.

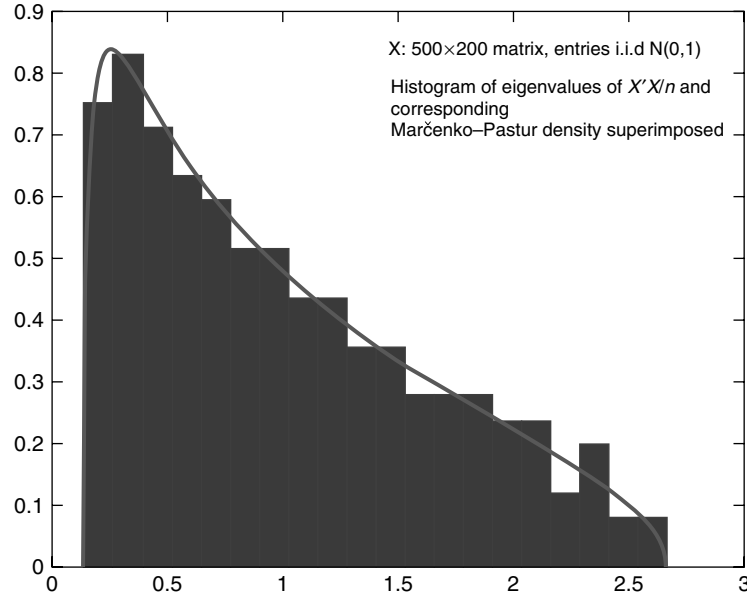

Figure 1 Density of Marčenko–Pastur law and histogram of eigenvalues. Here the histogram of eigenvalues of $X'X/n$ is plotted, for $p = 200$, $n = 500$. The entries of X are i.i.d $\mathcal{N}(0, 1)$. Since $\Sigma = \text{id}$, the “true” (or population) eigenvalues are all equal to 1, illustrating the fact that the sample covariance matrix is not a good estimator of the population covariance when $r \neq 0$. The curve is the theoretical prediction obtained from the Marčenko–Pastur law

“Bulk” results deal with the empirical distribution of the eigenvalues and study the convergence properties of this (random) probability measure. If $l_1 \geq l_2 \geq \dots \geq l_p$ denote the decreasingly ordered eigenvalues of the $p \times p$ matrix $\widehat{\Sigma}$, we call F_p the spectral distribution of $\widehat{\Sigma}$; by definition, we have

$$dF_p(x) = \frac{1}{p} \sum_{i=1}^p \delta_{l_i} dx \quad (3)$$

Here δ_x denotes a Dirac mass (of mass 1) at x . Note that F_p is a probability measure. Also, $F_p([x, \infty))$ is the proportion of eigenvalues of $\widehat{\Sigma}$ that are larger than x .

To study F_p in random matrix theory, it is common to use the Stieltjes transform of a distribution. By definition, the Stieltjes transform of a distribution G is a complex-valued function of one complex variable with strictly positive imaginary part, defined as

$$\begin{aligned} m_G(z) &= \int \frac{dG(x)}{x - z}, \text{ for } z \in \mathbb{C}^+ \\ &= \{z \in \mathbb{C} \text{ with } \text{Im}[z] > 0\} \end{aligned} \quad (4)$$

We note that m_G maps $\mathbb{C}^+$ into $\mathbb{C}^+$. The importance of Stieltjes transforms in this context comes from the fact that if F_p is a sequence of probability distributions and $m_{F_p}(z)$ converges, for all z in $\mathbb{C}^+$ to $m_F(z)$, where $m_F(z)$ is in $\mathbb{C}^+$, and $\lim_{y \rightarrow \infty} y m_F(iy) = -1$, then F_p converges weakly to F (and therefore F is a probability distribution). For a thorough introduction to the connection between convergence of Stieltjes transforms and convergence of probability distributions, we refer the reader to [15].

An important result concerning eigenvalues of sample covariance matrices is the following result shown in [26], which generalizes results in [21] and [29]. We note that the functional equation we are about to state was found first in [21] and is sometimes called the *Marčenko–Pastur* equation.

Theorem 1 (Silverstein [26]) *Let Y be an $n \times p$ matrix with i.i.d entries, denoted $Y_{i,j}$. Suppose that $Y_{i,j}$ has two moments, that is, $\mathbf{E}(Y_{i,j}^2) < \infty$, and variance 1. Let Σ_p be the population covariance matrix. In particular, Σ_p is positive semidefinite. Suppose the spectral distribution of Σ_p , H_p , has*

a limit, H , in the sense of weak convergence of distributions.

Let the data matrix be represented by $X = Y\Sigma_p^{1/2}$. Call F_p the spectral distribution of $X'X/n$ and m_p the Stieltjes transform of F_p . Call $v_p(z) = -(1 - p/n)/z + p/nm_p(z)$. (v_p is the Stieltjes transform of the spectral distribution of the matrix XX'/p .)

When $p/n \rightarrow r \neq 0$, F_p converges weakly almost surely (a.s.) to a deterministic (probability) distribution F . Moreover, $\forall z \in \mathbb{C}^+$, $v_p(z) \rightarrow v(z)$ a.s., and

$$-\frac{1}{v(z)} = z - r \int \frac{\lambda dH(\lambda)}{1 + \lambda v(z)} \quad (5)$$

It can be shown that there is a unique solution to the previous equation which is a Stieltjes transform.

Some comments are in order here. First, equation (5) relates the properties of the limit of the empirical spectral distribution (“encoded” by its Stieltjes transform in v) to those of the limiting population spectral distribution represented by H . Also, because finite rank perturbation of matrices does not affect limiting spectral distributions (see, for instance, [2]), the same result applies to the limiting spectral distribution of $(X - \bar{X})'(X - \bar{X})/n$, the sample covariance matrix used in practice. In other respects, the Marčenko–Pastur law can be obtained fairly simply from equation (5), as explained in [21] for instance. Finally, robustness properties (and lack thereof) of this functional equation have recently been investigated in [8], highlighting, in particular, geometric limitations for the data, implicitly implied by the model used in Theorem 1.

Properties of Extreme Eigenvalues

Limiting spectral distribution properties do not in general imply anything about properties of extreme eigenvalues, beside the fact that extreme eigenvalues need to be at the edge (or outside) of the support of the limiting spectral distribution. However, properties of these extreme eigenvalues are important in statistics, in particular for techniques such as principal component analysis (PCA; see [22]).

Results about extreme eigenvalues are available. An important one is for instance, when $\Sigma_p = \text{Id}_p$; then the largest eigenvalue of $X'X/n$ converges to $(1 + \sqrt{r})^2$. The result was first obtained in [14], and under weaker assumptions in [30]. We cite the latter result.

Theorem 2 (Yin et al. [30]) Suppose X is an $n \times p$ data matrix, with i.i.d entries. Suppose that $\mathbf{E}(X_{i,j}) = 0$, $\mathbf{E}(X_{i,j}^2) = 1$ and $\mathbf{E}(X_{i,j}^4) < \infty$. Suppose $p/n \rightarrow r \in (0, \infty)$, as $n \rightarrow \infty$. Then, we have, if $l_1(X'X/n)$ denotes the largest eigenvalue of $X'X/n$,

$$l_1\left(\frac{X'X}{n}\right) \rightarrow (1 + \sqrt{r})^2 \quad (6)$$

As explained in [25], the existence of the fourth moment is necessary for this result to hold. Similar convergence results exist concerning the smallest eigenvalue of $\hat{\Sigma}$ (see [3] and [2, p. 635]).

More recent theoretical work concerns fluctuation behavior of the largest eigenvalues of sample covariance matrices. Following mathematical breakthroughs in the 1990s (see [27]), it has become possible to describe the limiting distribution of $l_1(X'X/n)$. In particular, the papers [9, 13, 17, 18], show the following:

Theorem 3 Suppose X is an $n \times p$ matrix with i.i.d $\mathcal{N}(0, 1)$ entries. Suppose n and p tend to infinity. Then

$$n^{2/3} \frac{l_1(X'X/n) - (1 + \sqrt{p/n})^2}{(1 + \sqrt{p/n})(1 + \sqrt{n/p})^{1/3}} \Longrightarrow \text{TW}_1 \quad (7)$$

The most important part of the result (the case p/n having a finite nonzero limit) is shown in [18]. In the previous theorem, TW_1 is a Tracy–Widom distribution. Its density is known explicitly (see [28] and [18]).

In all the previous examples, $\Sigma_p = \text{Id}_p$. The case of general Σ is starting to be understood, too, and is more relevant to techniques such as PCA. The situation where Σ has a few isolated “large” eigenvalues and all the other eigenvalues are equal is now reasonably well understood (see [5, 23]). In this case, the empirical largest eigenvalue is biased and the bias can be computed explicitly. The corresponding sample eigenvector does not converge to the population eigenvector associated with the isolated eigenvalue. The situation where Σ is truly general is more complicated. A formula for the limit of the largest eigenvalue in certain class of population covariance matrices is given in [12], along with a notion of isolation of eigenvalues. Let us finally note that as described in [4] in a slightly different context (and partially generalized in [5]), if the population largest eigenvalue is not isolated (or large) enough,

the largest empirical eigenvalue will asymptotically not be affected by its existence. In other words, in this situation, the existence of an isolated population eigenvalue is not detected by looking at the empirical largest eigenvalue, something that is potentially problematic in PCA.

Estimation of Covariance Matrices

Because of the increased availability of larger dimensional datasets, and in part because of recent results in random matrix theory indicating that in high dimensions (i.e., p large and of the same order of magnitude as n) the sample covariance matrix is not a good estimator (or proxy) for the population covariance, there has been quite a bit of activity recently in statistics to try to come up with better estimators of population covariance.

The classic paper [16] (see also [1, Section 7.8]) has shown that one could improve estimation of Σ (i.e., decrease the expected squared error of the corresponding estimator) by using linear combinations of $\hat{\Sigma}$ and any positive semidefinite matrices. These methods are often called *shrinkage* methods in statistics. More recently, Ledoit and Wolf [20] showed they could improve estimation of Σ by shrinking $\hat{\Sigma}$ toward the identity. Their method amounts to adding a certain quantity to all eigenvalues of $\hat{\Sigma}$ and keeping the same eigenvectors to get a new estimator of Σ , $\tilde{\Sigma}$. Finally, the paper [19], in the context of Markowitz portfolio optimization, proposed to use random matrix results to also shrink the eigenvalues of $\hat{\Sigma}$, this time in a nonlinear fashion; after noting the similarity between part of the histogram of eigenvalues of a sample correlation matrix computed from financial data and the density of the Marčenko–Pastur law, the authors of [19] proposed to leave unchanged the eigenvalues falling outside the Marčenko–Pastur-looking part of the histogram, and to change those falling within it to a common value. They showed that this method improved on their dataset the predictive performance of the efficient frontier they obtained when solving the Markowitz optimization problem with Σ replaced by their estimate.

Other nonlinear methods for nonlinear shrinking of eigenvalues using random matrix theory have been proposed (see [11, 24]). Improved estimation of covariance matrices is at the moment an active topic of research in statistics [6, 7, 10], and while

it is not obvious that the results obtained there are immediately applicable in the financial context, some of the insights found in these papers might prove helpful in the future.

NOUREDDINE EL KAROUI

Convexity Adjustments

The notion of convexity adjustment (or convexity correction) in fixed income markets arises when one uses prices of standard (plain vanilla) products corrected by an *adjustment* to price nonstandard products.

Many fixed income products are nonstandard with respect to aspects such as the timing, the currency, or the rate of payment. Examples of such adjustments can be found in approximations for pricing formulae of products such as in-arrears or in-advance products, quanto products, constant maturity swaps (CMS) products, or equity swaps. Despite their nonstandard features, these products are quite similar to plain vanilla ones whose price can either be directly obtained from the market or at least computed in closed form. Thus, adjustments of plain vanilla prices can be understood as corrections needed to capture the bias introduced in prices by the complexities of the nonstandard products. Taking this effect into account correctly could provide financial institutions with a competitive advantage. Examples of particular interest for practitioners include

- yield convexity adjustments;
- forward *versus* futures price adjustments;
- modified schedule or timing adjustments; and
- mismatch between currencies or quanto adjustments.

The yield convexity adjustment is somewhat unrelated to the remaining adjustments, but it is probably the “original one” in the sense that it is related to the nonlinear (and convex) relationship between bond prices and their yield to maturity. The three remaining adjustments have traditionally been separated, both by practitioners and academics, as they concern different classes of products. Various *ad hoc* rules have been proposed in the literature to calculate a variety of convexity adjustments for different products. Many of them are, however, mutually inconsistent. Nonetheless, as we explain later, the last three adjustments can be understood as corrections resulting from the fact that by using quotes of plain vanilla products to price nonstandard ones, we are taking expectations under the “wrong” martingale measure. Pelsser [14] was the first to put convexity adjustments on a firm

mathematical basis by showing that they can be interpreted as the side effect of changes in probability measures. To understand this connection, recall that in a stochastic interest rate setting, the no arbitrage price π , at time t , of any derivative paying $\Phi(T)$ at maturity T is given by

$$\begin{aligned}\pi(t, \Phi) &= \mathbb{E}_t^Q \left[e^{-\int_t^T r_u du} \Phi(T) \right] \\ &= p(t, T) \mathbb{E}_t^T [\Phi(T)]\end{aligned}\quad (1)$$

where $p(t, T)$, denotes the price at time t of a pure discount bond with maturity T and $\mathbb{E}_t^Q[\cdot]$, $\mathbb{E}_t^T[\cdot]$, denote expectation under the risk-neutral and the T -forward measure, respectively, conditional on the information available at time t . When dealing with fixed income derivatives, given the nature of the underlying asset, we are in a stochastic interest rate setting by definition, and, consequently, we are ultimately interested in computing, $\mathbb{E}_t^T[\Phi(T)]$, that is, the expected value, under the T -forward measure where the *numeraire* is $p(t, T)$, of our payoff. In the trivial cases, when our payoff turns out to be a T -forward martingale, we immediately get $\mathbb{E}_t^T[\Phi(T)] = \Phi(t)$. Unfortunately, this is *not* the case in most situations. Even if our payoff is not a martingale under the appropriate T -forward measure, it could be a martingale under *some* martingale measure, $\mathbb{Q}^\Phi$. This is obviously a restrictive assumption, but as it turns out, it includes many popular interest rate products. Suppose, therefore, our payoff is a martingale under the $\mathbb{Q}^\Phi$ martingale measure. Then we know $\Phi(t) = \mathbb{E}_t^\Phi[\Phi(T)]$, and we can define the convexity adjustment as the term CC^Φ for which the following holds:

$$\mathbb{E}_t^T[\Phi(T)] = \Phi(t) + CC^\Phi(t) \quad (2)$$

From the martingale properties of our payoff we get $\Phi(t) = \mathbb{E}_t^\Phi[\Phi(T)] = \mathbb{E}_t^T[\Phi(T)\Lambda(T)]$, where Λ denotes the Radon–Nikodym derivative (with $\Lambda(t) = 1$). Clearly, the cases where we can say something about $\mathbb{E}_t^T[\Phi(T)\Lambda(T)]$ are the cases where we can say something about convexity adjustment terms CC^Φ , which is nothing but a side effect of measure changes. For details concerning Radon–Nikodym derivatives and their relation to measure changes, we refer to [6]. In the following, we address each type of adjustment separately.

Yield Convexity Adjustments

Consider a pure discount bond with maturity T . This section is based on a particular “ T -bond”, and to ease up notation we always suppress “ T ”. That is, we simply use $p(t)$, $y(t)$, to denote the spot price and yield to maturity of the T -bond. One of the most commonly used convexity adjustments results from the nonlinear relationship between the bond’s price and its yield to maturity $p(t) = G(y(t))$. See **Bond**. The exact functional form of G depends on capitalization assumptions, but it is always a continuous and convex function. Given a concrete G , one can define the forward bond yield, $y_f(t, S)$, as the yield satisfying $f(t, S) = G(y_f(t, S))$, where $f(t, S)$ is the forward price of a contract written on the T -bond and maturing at time S . Without loss of generality, we consider $t \leq S \leq T$. One way to approximate the price at some future time S of the T -bond is to use a second-order Taylor expansion around the $y_f(t, S)$ yield, that is,

$$p(S) = f(t, S) + G'(y_f(t, S)) [y(S) - y_f(t, S)] + \frac{1}{2} G''(y_f(t, S)) [y(S) - y_f(t, S)]^2 \quad (3)$$

We can then take expectations under the S -forward measure to obtain

$$\begin{aligned} \mathbb{E}_t^S [p(S)] &\approx f(t, S) \\ &+ G'(y_f(t, S)) \mathbb{E}_t^S [y(S) - y_f(t, S)] \\ &+ \frac{1}{2} G''(y_f(t, S)) \mathbb{E}_t^S [y(S) - y_f(t, S)]^2 \end{aligned} \quad (4)$$

As $f(t, S) = \mathbb{E}^S [p(S)]$, we immediately obtain

$$\begin{aligned} \mathbb{E}_t^S [y(S)] &\approx y_f(t, S) \\ &- \frac{1}{2} \frac{G''(y_f(t, S))}{G'(y_f(t, S))} \mathbb{E}^S [y(S) - y_f(t, S)]^2 \end{aligned} \quad (5)$$

and the second term on the right-hand side (RHS) is what is understood as convexity adjustment in this context. It results from the fact that future yields of T -bonds are not today’s yields from forward contracts on T -bonds.

A common step to get the convexity adjustment in closed form is to further assume that $\mathbb{E}^S [(y(S) - y_f(t, S))^2] = \sigma^2 y(t)^2 (S - t)$. This adjustment was first proposed in [4, 9] and later sharpened in [8], but it is hard to justify on theoretical grounds. Note that $\mathbb{E}_t^S [y(S)] \neq y_f(t, S)$, so $\mathbb{E}_t^S [(y(S) - y_f(t, S))^2]$ cannot be understood as some sort of variance of future yields.

Moreover, the above derived convexity adjustment is an obvious consequence of the Jensen inequality on convex functions, which tells us that for convex G , $\mathbb{E}[G(y)] > G(\mathbb{E}[y])$. The Jensen inequality is true under any measure, so, in particular, one could also use futures contracts on T -bonds. As mentioned earlier, we could define the futures bond yield, $y_F(t, S)$, as the yield satisfying $F(t, S) = G(y_F(t, S))$ and using the fact that $F(t, S) = \mathbb{E}^Q [p(S)]$ we would get $\mathbb{E}_t^Q [y(S)] \approx y_F(t, S) - \frac{1}{2} [G''(y_F(t, S))/G'(y_F(t, S))] \mathbb{E}_t^Q [y(S) - y_F(t, S)]^2$. Once again, this is hard to interpret, but at least it would have the advantage that futures quotes may be observed directly from the market.

Finally, it is difficult to justify why the expansion should be around the forward bond yield $y_f(t, S)$ and not directly around today’s yield $y(t)$.

In our opinion, a more sensible way to study the relationship between a T -bond price and its yield to maturity is to derive it directly from the dynamics of bond prices. For any risk-neutral “ T -bond” dynamics $dp(t) = r_t p(t) dt + v_t p(t) dW_t^Q$, no arbitrage arguments allow us to obtain the *exact* relationship. For instance, in the continuously compounded yield case, we get

$$\mathbb{E}_t^Q [y(S)] = y(t) - \frac{p(t, S) - \mathbb{E}_t^Q \left[\frac{1}{2} \int_t^S v_u^2 du \right]}{T - S} \quad (6)$$

where $p(t, S)$, as above, denotes the price at time t of an S -bond. The second term on the left-hand side (LHS) can be understood as a convexity correction, and for any deterministic volatility of bond prices it can be computed in closed form. In particular, this is true for any affine model.

Forward/Futures Adjustments

A second type of convexity adjustment occurs when we are interested in quoting forward prices on any given underlying while having available futures prices on the same underlying. Recall (*see Forwards and Futures*) that the difference between futures and forward prices results from the correlation between the underlying to the financial contract and the spot interest rate. As mentioned in [12], this correlation, capitalized by the margin calls of the futures contract, leads to a more expensive (respectively cheaper) futures contract in the case of positive (respectively negative) correlation. Let us denote by $f(t, T)$ and $F(t, T)$ the forward and futures prices for contracts with maturity T on any underlying, respectively. It is a well-known fact that forward prices with maturity T are martingales under the T -forward martingale measure, while futures prices are martingales under the Q risk-neutral measure. For further reading on forward martingale measures, we refer to [1]. The difference in both prices occurs only in a stochastic interest rate setting and is therefore of particular importance when dealing with fixed income products and derivatives. For concrete examples on the difference between futures and forward term structures in a quite general setting (including any affine model), we refer to [5].

Timing Adjustments

This third cause of adjustment occurs when an interest rate derivative is structured so that it does not incorporate the natural time lag. Examples of products with modified schedule not only are obviously in-arrears products but also include the case of the CMS rate where the floating rate is in itself a swap rate with a certain maturity, usually higher than the time interval until the next payment. The market practice concerning schedule bias is to distinguish between LIBOR rates related convexity adjustments and swap rate convexity adjustments. We follow market practice and present them separately.

LIBOR Convexity Adjustments. The forward LIBOR rate $L(t, T_{i-1}, T_i)$ can be expressed in terms of discount bond prices as

$$L(t, T_{i-1}, T_i) = \frac{1}{\alpha_i} \frac{p(t, T_{i-1}) - p(t, T_i)}{p(t, T_i)} \quad (7)$$

where $\alpha_i = T_i - T_{i-1}$. Spot LIBOR rates can be defined in terms of the forward ones as $L(t, T) = L(t, t, T)$. From the above expression, one can easily see the forward LIBOR rate $L(t, T_{i-1}, T_i)$ is a martingale under the forward martingale measure $\mathbb{Q}^{T_i}$. Thus, we can price future LIBOR-dependent payments due at T_i , using equation (1) and forward LIBOR rates quoted today as we have $\mathbb{E}_t^{T_i}[L(T_{i-1}, T_i)] = L(t, T_{i-1}, T_i)$. This is the case in standard swap contracts, for instance.

However, in LIBOR-in-arrears (LIA) contracts, the LIBOR payment is due in advance, at time T_{i-1} . This leads to defining the LIA convexity correction as

$$\mathbb{E}_t^{T_{i-1}}[L(T_{i-1}, T_i)] = L(t, T_{i-1}, T_i) + CC^{\text{LIA}}(t) \quad (8)$$

In this particular case, the measure change that we are interested in occurs between two forward measures and we have

$$\begin{aligned} \mathbb{E}_t^{T_{i-1}}[L(T_{i-1}, T_i)] \\ = \mathbb{E}_t^{T_i} \left[L(T_{i-1}, T_i) \frac{1 + \alpha_i L(T_{i-1}, T_i)}{1 + \alpha_i L(t, T_{i-1}, T_i)} \right] \end{aligned} \quad (9)$$

which implies

$$\begin{aligned} CC^{\text{LIA}}(t) \\ = \alpha_i \frac{\mathbb{E}_t^{T_i}[(L(T_{i-1}, T_i))^2] - [L(t, T_{i-1}, T_i)]^2}{1 + \alpha_i L(t, T_{i-1}, T_i)} \\ = \frac{\alpha_i \text{Var}_t[L(T_{i-1}, T_i)]}{1 + \alpha_i L(t, T_{i-1}, T_i)} \end{aligned} \quad (10)$$

This is valid irrespective of the distribution that we assume for the forward LIBOR rates. Moreover, it only depends on its variance, which is the same under any equivalent martingale measure. Reference [15] provides exact LIA convexity adjustments based upon the assumption of lognormal LIBOR rates as in LIBOR market models (*see LIBOR Market Model*). In that particular case, we get $CC^{\text{LIA}}(t) = \alpha_i (L(t, T_{i-1}, T_i))^2 e^{\sigma^2(T_{i-1}-t)} / (1 + \alpha_i L(t, T_{i-1}, T_i))$, where σ represents the LIBOR volatility taken as constant. More generally, it is also possible to find exact LIA convexity adjustments in the context of affine term structure models.

Swap Convexity Adjustments. Since interest rate swaps make up a big proportion of the over-the-counter (OTC) derivatives market, convexity corrections needed for CMS are of particular interest and deserve separate attention. CMS payoffs and related products are discussed in detail in **CMS spread products**.

We start by recalling that the forward swap rate $S(t, T_n, T_N)$ quoted at time t , with start date T_n and maturity T_N is model-free and equal to

$$S(t, T_n, T_N) = \frac{p(t, T_n) - p(t, T_N)}{P(t, T_n, T_N)} \quad (11)$$

where $P(t, T_n, T_N) = \sum_{i=n}^N \alpha_i p(t, T_i)$ for α_i as before, is a portfolio of bonds, sometimes known as *swap level*. It is well known that swap rates are martingales under the so-called swap martingale measure, here denoted by Q^S , and whose *numeraire* is the swap level.

A CMS exchanges a swap rate with a certain maturity c against a fixed payment K . The difficulty lies in computing the value of each payment of the floating leg. By no arbitrage, the value at time t of the payment due at T_i is given by $\alpha_i p(t, T_i) \mathbb{E}_t^{T_i} [S(T_{i-1}, T_i, T_{i+c})]$ where, as before, $\mathbb{E}_t^{T_i}[\cdot]$ denotes conditional expectation under the T_i -forward measure. As $S(T_{i-1}, T_i, T_{i+c})$ is not a martingale under forward measures, we need a convexity adjustment to take care of this. The convexity adjustment for each payment of a CMS can be defined as

$$\mathbb{E}_t^{T_i} [S(T_{i-1}, T_i, T_{i+c})] = S(t, T_i, T_{i+c}) + CC_t^{\text{CMS}}(t) \quad (12)$$

and it relies on measure changes from the T_i -forward measure to Q^S . Concretely we get,

$$\begin{aligned} CC_t^{\text{CMS}} &= \frac{P(t, T_i, T_{i+c})}{p(t, T_i)} \\ &\times \mathbb{E}_t^S \left[S(T_{i-1}, T_i, T_{i+c}) \frac{p(T_{i-1}, T_i)}{P(T_{i-1}, T_i, T_{i+c})} \right] \\ &- S(t, T_i, T_{i+c}) \end{aligned} \quad (13)$$

This is not easy to obtain in closed form. Most CMS convexity adjustment formulas can only be obtained in an approximative way. A common practice at this

stage is to see $p(t, T_i)/P(t, T_i, T_{i+c})$ as a function G of the swap rate $S(t, T_i, T_{i+c})$.

In the case of the linear swap model (LSM) introduced in [10], G is linear and we have $p(t, T_i)/P(t, T_i, T_{i+c}) = G(S(t, T_i, T_{i+c})) = A + B(T_i)S(t, T_i, T_{i+c})$ for $A = (\sum_i \alpha_i)^{-1}$ a constant and $B(T_i) = [p(t, T_i)/P(t, T_i, T_{i+c}) - A]/S(t, T_i, T_{i+c})$ only dependent on T_i . This linearity assumption is a crude one, but it yields better results in practice than one would expect. The reason for this is that convexity adjustments only become sizable for long maturities, and, for those maturities the term structure movements tend to be parallel. Thus, they are well captured by a linear model.

Alternatively, we can consider a generic (truly convex) function G , expand it around today's swap rate $S(t, T_i, T_{i+c})$ using a Taylor expansion to then take expectations. Reference [7] is a popular paper on convexity adjustments of CMS swaps, caps, and floors that follows this line. The author analyzes three basic term structure models, starting from a standard yield curve model and continuing to more sophisticated models, which account for nonparallel shifts and continuous time compounding of interest rates. This is equivalent to assuming particular functional forms for the G function. Given a functional for G , the author then uses a first-order Taylor approximation and a lognormal distribution for the swap rates to approximations for the convexity adjustments of CMS

$$\begin{aligned} CC_t^{\text{CMS}} &\approx S(t, T_i, T_{i+c}) \frac{G'(S(t, T_i, T_{i+c}))}{G(S(t, T_i, T_{i+c}))} \\ &\times \left[S(t, T_i, T_{i+c}) e^{\sigma^2(T_{i-1}-t)} - 1 \right] \end{aligned} \quad (14)$$

where σ can be taken to be [2] implied volatility from at-the-money vanilla swaptions market quotes. For convexity adjustments of CMS caps and floors, we refer to the paper itself. For more information on popular formulation of swap rate dynamics, see **Swap Market Models**.

The method proposed in [7] includes the LSM as a special case, in which the first-order Taylor approximation is, in fact, exact. Depending on the underlying dynamics for the swap rate, the formulas may be quite evolved, but the paper [16] provides hope for nice formulas in the affine term structure setup.

Quanto Adjustments

So far, we have discussed timing adjustments. Quanto products refer to products with an underlying expressed in one currency and payment in a different currency. Quanto adjustments are adjustments that try to correct for payment in the “wrong currency” *versus* the “wrong timing”. We can have quanto (diff) swaps, swaptions, caps, floors, CMS rates, barrier options, equity swaps, and so on. For an overview of existing quanto products, see **Quanto Options**.

As explained in [14], a convexity adjustment of this type occurs when our product is a martingale under the foreign risk-neutral measure, but needs to be priced under the domestic risk-neutral measure. As an example, we shall use a diffed LIBOR contract, that is, a contract where the foreign LIBOR rate $L^f(T_{i-1}, T_i)$ is observed at T_{i-1} and is paid in domestic currency at time T_i . This contract can serve as the floating payment for a differential swap (also known as *diff swap* or *quanto swap*), and it is made against a fixed payment in domestic currency. We know that the forward LIBOR rate $L^f(t, T_{i-1}, T_i)$ is a martingale under the foreign T_i forward measure Q^{f, T_i} , so $L^f(t, T_{i-1}, T_i) = \mathbb{E}_t^{f, T_i}[L^f(T_{i-1}, T_i)]$, but we need to compute the expectation of the foreign LIBOR rate under the domestic forward measure. Under that measure we know

$$\mathbb{E}_t^{d, T_i}[L^f(T_{i-1}, T_i)] = L^f(t, T_{i-1}, T_i) + CC^{\text{diff}}(t) \quad (15)$$

and this type of convexity adjustment is given by

$$CC^{\text{diff}}(t) = \frac{\mathbb{E}_t^{f, T_i}[L^f(T, T_i)F(T_{i-1}, T_i)]}{F(t, T_i)} - L^f(t, T_{i-1}, T_i) \quad (16)$$

where $F(t, T_i)$ is the forward exchange rate (f/d), quoted at t and with delivery at T_i . The convexity correction for quanto products will typically depend on the correlation between the foreign interest rate and the exchange rate. If, in the above example, both the forward LIBOR and the forward exchange rates have lognormal distributions under Q^{f, T_i} as proposed in [11], one can easily derive the convexity adjustment formula as $CC^{\text{diff}}(t) = L^f(t, T_{i-1}, T_i) [e^{\rho_{F,L}\sigma_L\sigma_F(T_{i-1}-t)} - 1]$, where $\rho_{F,L}$ is the instant correlation between the LIBOR and the forward exchange rate, σ_L is the volatility of the LIBOR,

and σ_F is the volatility of the forward exchange rate, assumed to be constant.

Algorithmic Trading

Technology continues to have an increasingly significant impact on how securities are traded in today's markets. Many trading floors have been replaced by electronic trading platforms and more than a third of the trading volume in the United States can be attributed to algorithmic trading. Every large broker-dealer provides algorithmic trading services to their institutional clients in order to assist their trading. The algorithms used by institutional investors, hedge funds, and many other market participants are used to make trading decisions about the timing, price, and size of trades, with the objective of reducing risk-adjusted costs.

In a broad sense, the term *algorithmic trading* is used to describe trading in an automated manner according to a set of rules. It is often used interchangeably with statistical trading or statistical arbitrage, which may or may not be automated, but is based on signals derived from statistical analyses or models. Smart order routing, program trading, and rules-based trading are some of the other terms associated with algorithmic trading. More recently, the range of functions and activities associated with algorithmic trading has grown to include market impact modeling, execution risk analytics, cost aware portfolio construction, and the use of market microstructure effects.

In this article, we first explain the basic ideas of market impact and optimal execution from both the sell- and buy-side perspectives. We then provide an overview of the most popular algorithmic trading strategies.

Market Impact and the Order Book

The limit order book contains resting limit orders. These orders rest in the book and provide liquidity as they wait to be matched with nonresting orders, which represent a demand for liquidity. The three most common types of nonresting orders are marketable limit orders, market orders, and fill-or-kill orders.

The bid side of the limit book contains resting bids to buy a certain number of shares of stock at a certain price. The offer side contains resting offers to sell a certain number of shares of stock at a certain price.

A market order is a demand for an immediate execution of a certain number of shares at the best possible price. To get the best possible price, a market order sweeps through one side of the limit order book—starting with the best price—matching against resting orders until the full quantity of the market order is filled or the book is completely depleted.

Unlike a market order, a marketable limit order can be executed only at a specified price or better. For example, a marketable limit order to buy 100 shares at \$90.01 can match with a resting limit order to sell 200 shares at \$90.00. The trade print—the price at which the trade would take place—would be \$90.00.

The following examples illustrate how market orders to sell interact with resting limit orders to buy.

Figure 1 shows the idealized market impact of a 200-share market order to sell. The x - and y -axes display the time and price, respectively.

The bid side of the limit order book contains bids to buy a certain number of shares of stock at a certain price. Resting limit orders—orders that sit in the order book—are said to *provide liquidity* by mitigating the market impact of orders that must be filled immediately. The state of the book establishes a pretrade equilibrium (1), which is disturbed by a market order to sell 200 shares (2). Market orders must be filled immediately, and therefore represent a demand for liquidity.

As the sell order depletes the bid book by matching with limit orders to buy, it obtains an increasingly less favorable (lower) trade price, resulting in the trade print (3). Assuming no other trading activity, over time, liquidity providers replenish the bid book to (4), which is the posttrade equilibrium.

The difference between (4) and (1) is an information-based effect called *permanent market impact*. It is the market's response to information that a market participant has decided not to own 200 shares of this stock. This effect is typically modeled as immediate and linear in the total number of shares executed. Huberman and Stanzl [9] show that, if the effect were not linear and immediate, buying and selling at two different rates could produce an arbitrage profit.

The difference between (4) and (3) is called *temporary market impact*. The trader who initiated the trade is willing to obtain a less favorable fill price (3) to get his/her trade done immediately. This *cost*

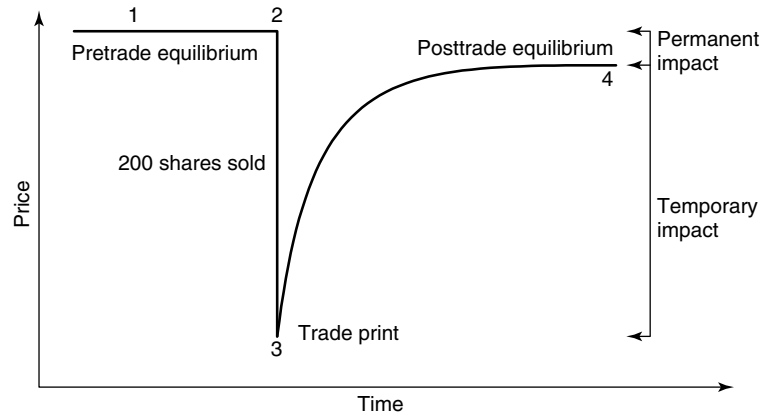

Figure 1 Idealized market impact model showing sell of 200 shares

of immediacy is typically modeled as linear or square root. Under the assumption of square root impact, with all other factors held constant, a trade of 200 shares executed over the same period of time as a trade of 100 shares would have square root of two times more temporary impact per share.

Figure 2 shows what would happen if the same trader were willing to wait some time between trades. The trade print from the previous figure is shown as a reference point (1). As in Figure 1, a pretrade equilibrium (2) is disturbed by a 100-share market order to sell (3). As the market order depletes the bid book by matching with limit orders to buy, it obtains a fill price (4). Over time (5), liquidity providers refill the bid book with limit orders to buy. However, the new posttrade equilibrium (6) is lower

than the pretrade equilibrium because it incorporates the information of the executed market order.

Our trader then places another market sell order for 100 shares (6) and obtains a trade print (7). Over time, the temporary impact—(8) minus (7)—decays and results in a new posttrade equilibrium (8). As the permanent impact is assumed to be linear and immediate, the posttrade equilibrium is shown to be the same for one order of 200 shares as it is for two orders of 100 shares each.

Optimal Execution

While our trader waits between trades (5), he/she incurs price risk—the risk that his/her execution will

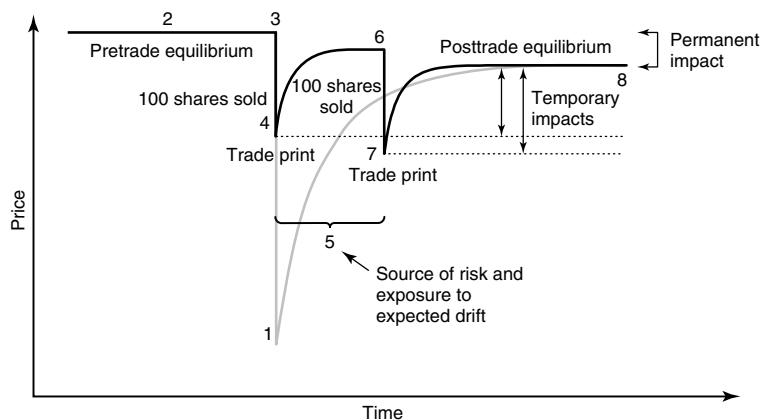

Figure 2 Idealized market impact model showing two sells of 100 shares each

be less favorable due to the random movement of prices. In this context, a *shortfall* is the difference between the effective execution price and the arrival price—the prevailing price at the start of the execution period. If we use the variance of *shortfalls* as a proxy for risk, a trader's aversion to risk establishes a risk/cost trade-off. In the first scenario, he/she pays a higher cost—the difference between (8) and (1)—to eliminate risk. In the second scenario, he/she pays a lower cost—the average of the differences between (8) and (4), and (8) and (7)—but takes on a greater dispersion of shortfalls associated with the waiting time between trades (5). This is the trade-off considered in the seminal paper of Almgren and Chriss [1].

Risk aversion increases a trader's sense of urgency and makes it attractive to pay some premium to reduce risk. The premium the trader pays is in the form of higher temporary market impact. All other factors held constant, a higher expected temporary market impact encourages slower trading, while a higher expected risk or risk aversion encourages faster trading.

Risk aversion embodies the notion that people dislike risk. For a risk-averse agent, the utility of a fair game, $u(G)$, is less than the utility of having the expected value of the game, $E(u(G))$, with certainty. The degree of risk aversion may be captured by the risk aversion parameter λ , which is used to translate risk into a *certain dollar cost equivalent*—the smallest certain dollar amount that would be accepted instead of the uncertain payoff from the fair game. For an agent with quadratic utility, the certain dollar cost equivalent is given by $E(G) - \lambda \text{Var}(G)$. Hence, his/her degree of risk aversion is characterized by the family of risk/return pairs with the same constant trade-off between the expected return and risk. An annualized target return and standard deviation imply a risk aversion, and may be translated to a risk aversion parameter of the type used in some optimal execution algorithms.

Another factor that influences the decision to trade more quickly or more slowly is the expectation of price change. For the purpose of execution, a *positive alpha* is an expectation of profits per share per unit time for unexecuted shares. A faster execution captures more of the profits associated with this expectation of price change. A *negative alpha* is the expectation of losses per share per unit time for unexecuted shares. A slower execution incurs less of

the losses associated with this expectation of price change.

For example, a trader has positive alpha if he/she expects prices to move lower while he/she is executing his/her sell orders. He/she may choose to front-weight his/her trade schedule—execute more rapidly at the beginning of the execution period—to obtain better execution prices. Similarly, a seller who believes that prices are moving higher may back-weight his/her trade schedule or delay the execution.

The general form of the optimal execution problem involves finding of the best trade-off between the effects of risk, market impact, and alpha by minimizing risk-adjusted costs relative to a prespecified benchmark. Common benchmarks are volume-weighted average price (VWAP) and arrival price (the price prevailing at the beginning of the execution period).

The first formulations of this problem go back to the seminal papers of Bertsimas and Lo [4] and Almgren and Chriss [1]. Assuming a quadratic utility function, a general formulation of this problem takes the form

$$\min_{x_t} [E(C(x_t)) + \lambda \text{Var}(C(x_t))] \quad (1)$$

where $C(x_t)$ is the cost of deviating from the benchmark. The solution is given by the trade schedule x_t that represents the number of shares that remains to buy/sell at time t . The trader's optimal trade schedule is a function of his/her level of risk aversion, $\lambda \geq 0$, which determines his/her urgency to trade, and dictates the preferred trade-off between execution cost and risk.

In the following two subsections, we describe the sell-and buy-side perspectives of the typical arrival price optimal execution models.

The Sell-side Perspective

The typical optimal execution model uses arrival price as a benchmark and balances the trade-off between market impact, price risk, and opportunity cost. Alpha is assumed to be greater than or equal to zero, which means that delaying execution may carry an associated opportunity cost, but does not carry an expectation of profit. The optimal strategy lies somewhere between two extremes: (i) trade everything immediately at a known cost or (ii) reduce market

impact by spreading the order into smaller trades over a longer horizon at the expense of increased price risk and opportunity cost.

Bertsimas and Lo [4] proposed an algorithm for the optimal execution problem that finds the minimum expected cost of trading over a fixed period of time for a risk neutral trader, $\lambda = 0$, facing an environment where price movements are assumed to be serially uncorrelated.

Almgren and Chriss [1] extended this concept using quadratic utility to embody the trade-off between the expected cost and price risk. The more aggressive (passive) trade schedules incur higher (lower) market impact costs and lower (higher) price risk. Similar to classical portfolio theory, as λ varies the resulting set of points $(Var(\lambda), E(\lambda))$ traces out the *efficient frontier of optimal trading strategies*. The two extreme cases $\lambda = 0$ and $\lambda \rightarrow \infty$ correspond to the minimum impact strategy—trading at a constant rate throughout the execution period—and the minimum variance strategy—a single execution of the entire target quantity at the start of the execution period.

Let us consider selling X shares, that is, we want $x_0 = X$ and $x_T = 0$. Under the assumptions that asset prices follow an arithmetic Brownian motion, permanent impact is immediate and linear in total shares executed, and temporary impact is linear in the rate of trading, the solution of the Almgren and Chriss model is

$$x_t = X \frac{\sinh(\kappa(T - t))}{\sinh(\kappa T)} \quad (2)$$

where $\kappa = \sqrt{\frac{\lambda\sigma^2}{\eta}}$. Here, σ and η represent stock volatility and linear temporary market impact cost.

Note that the solution is effectively a decaying exponential $X \exp(-\kappa t)$ adjusted such that $x_T = 0$. It does not depend on the permanent market impact, consistent with the discussion in the previous section. The urgency of trading is embodied in κ . This parameter determines the speed of liquidation independent of the order size X . For a higher risk aversion parameter or volatility—for example, representing increased perceived risk—the speed of trading increases as well. We also see that for a higher expected temporary market impact cost, the speed of trading decreases.

Impact Models

An impact model is used to predict changes in price due to trading activity. This expectation of price change may be used to inform execution and portfolio construction decisions. Several well-known models have been proposed. For example, see Hasbrouck [8], Lillo *et al.* [12], and Almgren *et al.* [3].

Almgren *et al.* use a proprietary data set obtained from Citigroup's equity trading desk in which a trade's direction (buyer or seller initiated) is known. Note that for most public data sets, trade direction is not available and has to be estimated by a classification algorithm. Classification errors in algorithms such as Lee and Ready [11], and Ellis *et al.* [5] introduce a bias that produces an overestimate of the true trading cost.

In Almgren *et al.*, trades serve as a proxy for trading imbalance. The authors assume that, some time after the complete execution of a parent order, only permanent impact remains. This allows them to separate impact into its temporary and permanent components.

The model parameters can then be calculated from a regression, giving the following results. First, permanent impact cost is linear in trade size and volatility. Second, temporary impact cost is linear in volatility and roughly proportional to the square root—Almgren *et al.* find a power 3/5—of the fraction of volume represented by one's own trading during the period of execution. Hence, for a given rate of trading, a less volatile stock with large average daily volume has the lowest temporary impact costs.

The Buy-side Perspective

Optimal execution algorithms have less value to a typical portfolio manager if analyzed separately from the corresponding returns earned by his/her trading strategy. In fact, high transaction costs are not bad *per se*—they could simply prove to be necessary for generating superior returns. At present, the typical sell-side perspective of algorithmic trading does not take expectation of profits or the client's portfolio objectives into account. Needless to say, this is an important component of execution.

The decisions of the trader and the portfolio manager are based on different objectives. The trader decides on the timing of the execution, breaking

large parent orders into a series of child orders that, when executed over time, represent the correct trade-off between opportunity cost, market impact, and risk. The trader sees only the trading assets, whereas the portfolio manager sees the entire portfolio, which includes both, the trading assets and the static—nontrading—positions.

The portfolio manager's task is to construct a portfolio by optimizing the trade-off between the opportunity cost, market impact, and risk for the full set of trading and nontrading assets. In general, the optimal execution framework described by Almgren and Chriss is not appropriate for the portfolio manager.

Engle and Ferstenberg [6] proposed a framework that unites these objectives by combining optimal execution and classical mean–variance optimization models. In their model, trading takes place at discrete time intervals as the portfolio manager rebalances his/her portfolio holdings w_t at times $t = 0, 1, \dots, T$ subject to changing expected returns, μ_t , and risk (as measured by the covariance matrix of returns), Ω_t , until he/she reaches the portfolio that reflects his/her final view $w_T = \frac{1}{2\lambda} \Omega_T^{-1} \mu_T$. The joint dynamic optimization problem has the form

$$\begin{aligned} \max_{\{w_t\}} \left\{ \sum_{t=1}^T (w_t^T \mu_t - \lambda w_t^T \Omega_t w_t) \right. \\ \left. - \sum_{t=1}^T \{ \Delta w_t^T \tau_t + (w_t - w_{t-1}) \mu_t \right. \\ \left. + \lambda (w_t - w_{t-1}) \Omega_t (w_t - w_{t-1}) \right\} \\ \left. + 2\lambda \sum_{t=1}^T (w_t - w_{t-1}) \Omega_t w_t \right\} \quad (3) \end{aligned}$$

where $\tau_t = \tau_t(\Delta w_t)$ is the temporary market impact function (for simplicity of exposition, we ignore permanent impacts). This is a dynamic programming problem that has to be solved by numerical techniques.

Each one of the three terms in the objective function above has an intuitive interpretation. The first term represents the standard mean–variance optimization problem. The second term corresponds to the optimal execution problem. The third term is the covariance between the remaining shares to be traded and the final position. In the single asset case, the third term is positive (negative) for buying

(selling) orders, which implies that risk is reduced (increased). If this term is ignored, which occurs when portfolio allocation and optimal execution are performed separately, then the measurement of total risk is biased.

Popular Algorithmic Trading Strategies

A small number of execution strategies have become *de facto* standards and are offered by most technology providers, banks, and institutional broker/dealers. However, even among these standards, the large number of input parameters makes it difficult to compare execution strategies directly.

Typically, a strategy is motivated by a *theme* or *style* of trading. The objective is to minimize either absolute or risk-adjusted costs relative to a *benchmark*. For strategies with mathematically defined objectives, an *optimization* is performed to determine how to best use the strategy to maximize a trader's or portfolio manager's utility. A *trade schedule*—or *trajectory*—is planned for strategies with a target quantity of shares to execute. The *order placement* engine—sometimes called the *micro-trader*—translates from a strategy's broad objectives to individual orders. User-defined *input parameters* control the trade schedule and order placement strategy.

In this section, we review some of the most common algorithmic trading strategies.

Volume-weighted Average Price

Six or seven years ago, the VWAP execution strategy represented the bulk of algorithmic trading activity. Currently, it is second in popularity only to arrival price. The appeal of benchmarking to VWAP is that the benchmark is easy to compute and intuitively accessible.

The typical parameters of a VWAP execution are the start time, the end time, and the number of shares to execute. Additionally, optimized forms of this strategy require a choice of risk aversion.

The most basic form of VWAP trading uses a model of the fractional daily volume pattern over the execution period. A trade schedule is calculated to match this volume pattern. For example, if the execution period is one day, and 20% of a day's volume is expected to be transacted in the first hour,

a trader using this basic strategy would trade 20% of his/her target accumulation or liquidation in the first hour of the day. Since the daily volume pattern has a U shape—with more trading in the morning and afternoon and less in the middle of the day—the volume distribution of shares executed in a VWAP pattern would also have this U shape.

VWAP is an ideal strategy for a trader who meets all of the following criteria:

- his/her trading has little or no alpha during the execution period;
- he/she is benchmarked against the VWAP;
- he/she believes that market impact is minimized when his/her own rate of trading represents the smallest possible fraction of all trading activity; and
- he/she has a set number of shares to buy or sell.

Deviation from these criteria may make VWAP strategies less attractive. For example, market participants who trade over the course of a day and have strong positive alpha may prefer a front-weighted trajectory, such as those that are produced by an arrival price strategy.

The period of a VWAP execution is most typically a day or a large fraction of a day. Basic VWAP models predict the daily volume pattern using a simple historical average of fractional volume. Several weeks to several months of data are commonly used. However, this forecast is noisy. On any given day, the actual volume pattern deviates substantially from its historical average, complicating the strategy's objective of minimizing its risk-adjusted cost relative to the VWAP benchmark. Some models of fractional volume attempt to increase the accuracy of volume pattern prediction by making dynamic adjustments to the prediction based on observed trading results throughout the day.

Several variations of the basic VWAP strategy are common. The ideal VWAP user (as defined earlier) can lower his/her expected costs by increasing his/her exposure to risk relative to the VWAP benchmark. For example, assuming an alpha of zero, placing limit orders throughout the execution period and catching up to a target quantity with a market order at the end of the execution period will lower the expected cost while increasing risk. This is the highest risk strategy. Continuously placing small market orders in the fractional volume pattern is the lowest risk strategy,

but has a higher expected cost. For a particular choice of risk aversion, somewhere between the highest and lowest risk strategies, is a compromise optimal strategy that perfectly balances risk and costs.

For example, a risk-averse VWAP strategy might place one market order of 100 shares every 20 s, whereas a less risk-averse strategy might place a limit order of 200 shares, and, 40 s later, place a market order for the difference between the desired fill of 200 and the actual fill (which may have been smaller). The choice of the average time between market orders in a VWAP execution implies a particular risk aversion.

For market participants with a positive alpha, a frequently used rule-of-thumb optimization is compressing trading into a shorter execution period. For example, a market participant may try to capture more profits by doing all of his/her VWAP trading in the first half of the day instead of taking the entire day to execute.

In another variant of VWAP—*guaranteed VWAP*—a broker commits capital to guarantee his/her client the VWAP price in return for a pre-determined fee. The broker takes on a risk that the difference between his/her execution and VWAP will be greater than the fee he/she collects. If institutional trading volume and individual stock returns were uncorrelated, the risk of guaranteed VWAP trading could be diversified away across many clients and many stocks. In practice, managing a guaranteed VWAP book requires some complex risk calculations that include modeling the correlations of institutional trading volume.

Time-weighted Average Price

The time-weighted average price (TWAP) execution strategy attempts to minimize market impact costs by maintaining an approximately constant rate of trading over the execution period. With only a few parameters—start time, end time, and target quantity—TWAP has the advantage of being the simplest execution strategy to implement. As with VWAP, optimized forms of TWAP may require a choice of risk aversion. Typically, the VWAP or arrival price benchmarks are used to gauge the quality of a TWAP execution. TWAP is hardly ever used as its own benchmark.

The most basic form of TWAP breaks a parent order into small child orders and executes these child orders at a constant rate. For example, a parent order

of 300 shares with an execution period of 10 min could be divided into three child orders of 100 shares each. The child orders would be executed at the 3:20, 6:40, and 10:00 min marks. Between market orders, the strategy may place limit orders in an attempt to improve execution quality.

An ideal TWAP user has almost the same characteristics as an ideal VWAP user, except that he/she believes that the lowest *trading rate*—not the lowest *participation rate*—incurs the lowest market impact costs.

TWAP users can benefit from the same type of optimization as VWAP users by placing market orders less frequently, and using resting limit orders to attempt to improve execution quality.

Participation

The participation strategy attempts to maintain a constant fractional trading rate. That is, its own trading rate as a fraction of the market's total trading rate should be constant throughout the execution period. If the fractional trading rate is maintained exactly, participation strategies cannot guarantee a target fill quantity.

The parameters of a participation strategy are the start time, end time, fraction of market volume the strategy should represent, and max number of shares to execute. If the max number of shares is specified, the strategy may complete execution before the end time. Along with VWAP and TWAP, participation is a popular form of nonoptimized strategies, though some improvements are possible with optimization.

VWAP and arrival price benchmarks are often used to gauge the quality of a participation strategy execution. The VWAP benchmark is particularly appropriate because the volume pattern of a perfectly executed participation strategy is the market's volume pattern during the period of execution. An ideal user of participation strategies has all of the same characteristics as an ideal user of VWAP strategies, except that he/she is willing to forego certain execution to maintain the lowest possible fractional participation rate.

Participation strategies do not use a trade schedule. The strategy's objective is to participate in volume as it arises. Without a trade schedule, a participation strategy cannot guarantee a target fill quantity. The most basic form of participation strategies waits for

trading volume to show up on the tape, and follows this volume with market orders. For example, if the target fractional participation rate is 10%, and an execution of 10 000 shares is shown to have been transacted by other market participants, a participation strategy would execute 1000 shares in response.

Unlike a VWAP trading strategy, which for a given execution may experience large deviations from an execution period's actual volume pattern, participation strategies can closely track the actual—as opposed to the predicted—volume pattern. However, close tracking has a price. In the earlier example, placing a market order of 1000 shares has a larger expected market impact than slowly following the market's trading volume with smaller orders. An optimized form of the participation strategy amortizes the trading shortfall over some period of time. Specifically, if an execution of 10 000 shares is shown to have been transacted by other market participants, instead of placing 1000 shares all at once, a 10% participation strategy might place 100 share orders over some period of time to amortize the shortfall of 1000 shares. The result is a lower expected shortfall, but a higher dispersion of shortfalls.

Market-on-close

The market-on-close strategy is popular with market participants who either want to minimize risk-adjusted costs relative to the closing price of the day or want to manipulate—*game*—the close to create the perception of a good execution. The ideal market-on-close user is benchmarked to the close of the day and has low or negative alpha. The parameters of a market-on-close execution are the start time, the end time, and the number of shares to execute. Optimized forms of this strategy require a risk-aversion parameter.

When market-on-close is used as an optimized strategy, it is similar in its formulation to an arrival price strategy. However, with market-on-close, a back-weighted trade schedule incurs less risk than a front-weighted one. With arrival price, an infinitely risk averse trader would execute everything in the opening seconds of the execution period. With market-on-close, an infinitely risk averse trader would execute everything at the closing seconds of the day. For typical levels of risk aversion, some trading would take place throughout the execution period. As with arrival price optimization, positive alpha

increases urgency to trade and negative alpha encourages delayed execution.

In the past, market-on-close strategies were used to manipulate—or *game*—the close, but this has become less popular as the use of VWAP and arrival price benchmarks have increased. Gaming the close is achieved by executing rapidly near the close of the day. The trade print becomes the closing price or very close to it, and hence shows little or no shortfall from the closing price benchmark. The true cost of the execution is hidden until the next day when temporary impact dissipates and prices return to a new equilibrium.

Arrival Price

The arrival price strategy—also called the *implementation shortfall* strategy—attempts to minimize risk-adjusted costs using the arrival price benchmark. Arrival price optimization is the most sophisticated and popular of the commonly used algorithmic trading strategies.

The ideal user of arrival price strategies has the following characteristics:

- he/she is benchmarked to the arrival price;
- he/she is risk averse and knows his/her risk aversion parameter;
- he/she has high positive or high negative alpha; and
- he/she believes that market impact is minimized by maintaining a constant rate of trading over the maximum execution period while keeping trade size small.

Most implementations are based on some form of the risk-adjusted cost minimization introduced by Almgren and Chriss [1]. In the most general terms, an arrival price strategy evaluates a series of trade schedules to determine which one minimizes risk-adjusted costs relative to the arrival price benchmark. As discussed in the section on optimal execution, under certain assumptions, this problem has a closed form solution.

The parameters in an arrival price optimization are alpha, number of shares to execute, start time, end time, and a risk aversion parameter. For buyers (sellers), positive (negative) alpha encourages faster trading. For both buyers and sellers, risk encourages faster trading, while market impact costs encourage slower trading.

For traders with positive alpha, the feasible region of trade schedules lies between the immediate execution of total target quantity and a constant rate of trading throughout the execution period.

A more general form of arrival price optimization allows for both the buyers and sellers to have either positive or negative alpha. For example, under the assumption of negative alpha, shares held long and scheduled for liquidation are—without considering one's own trading—expected to go up in price over the execution period. This would encourage a trader to delay execution or stretch out trading. Hence, the feasible region of solutions that account for both positive and negative alpha includes back-weighted as well as front-weighted trade schedules.

Other factors that necessitate back-weighted trade schedules in an arrival price optimization are expected changes in liquidity and expected crossing opportunities. For example, an expectation of a cross later in the execution period may provide enough cost savings to warrant taking on some price risk and the possibility of a compressed execution if the cross fails to materialize. Similarly, if market impact costs are expected to be lower later in the execution period, a rational trader may take on some risk to obtain this cost savings.

A variant of the basic arrival price strategy is *adaptive arrival price*. A favorable execution may result in a windfall in which an accumulation of a large number of shares takes place at a price significantly below the arrival price. This can happen by random chance alone. Almgren and Lorenz [2] demonstrated that a risk-averse trader should use some of this windfall to reduce the risk of the remaining shares. He/she does this by trading faster and thus incurring a higher market impact. Hence, the strategy is adaptive in that it changes its behavior based on how well it is performing.

Crossing

Though crossing networks have been around for some time, their use in algorithmic trading strategies is a relatively recent development. The idea behind crossing networks is that large limit orders—the kind of orders that may be placed by large institutional traders—are not adequately protected in a public exchange. Simply displaying large limit orders in the open book of an electronic exchange may

leak too much information about institutional traders' intentions. This information is used by prospective counterparties to trade more passively in the expectation that time constraints will force traders to replace some or all of the large limit orders with market orders. In other words, information leakage encourages *gaming* of large limit orders. Crossing networks are designed to limit information leakage by making their limit books opaque to both their clients and the general public.

A popular form of cross is the *midquote cross*, in which two counterparties obtain a midquote fill price. The midquote is obtained from a reference exchange, such as the NYSE or other public exchange. Regulations require that the trade is then printed to a public exchange to alert other market participants that it has taken place. The cross has no market impact but both the counterparties pay a fee to the crossing network. These fees are typically higher than the fees for other types of algorithmic trading because the market impact savings are significant while the fee is contingent on a successful cross.

More recently, crossing networks have offered their clients the ability to place limit orders in the crossing networks' dark books. Placing a limit order in a crossing network allows a cross to occur only at a certain price. This makes crossing networks much more like traditional exchanges, with the important difference that their books are opaque to market participants.

To protect their clients from price manipulation, crossing networks implement antigaming logic. As previously explained, opaqueness is itself a form of antigaming, but there are other strategies. For example, some crossing networks require orders to be above a minimum size or to remain in the network longer than a prespecified minimum time. Other networks will cross only orders of similar size. This prevents traders from ping-pong—sending small orders to the network to determine which side of the network's book has an order imbalance.

Another approach to antigaming prevents crosses from taking place during periods of unusual market activity. The assumption is that some of this unusual activity is caused by traders trying to manipulate the spread in the open markets to get a better fill in a crossing network.

Some networks also attempt to limit participation by active traders, monitoring their clients' activities

to see if their behavior is more consistent with normal trading than with gaming.

There are several different kinds of crossing networks. A *continuous crossing network* constantly sweeps through its book in an attempt to match buy orders with sell orders. A *discrete crossing network* specifies points in time when a cross will take place, say every half hour. This allows market participants to queue up in the crossing network just prior to a cross instead of committing resting orders to the network for extended periods of time. Some crossing networks allow scraping—a one time sweep to see if a single order can find a counterparty in the crossing network's book—while others allow only resting orders.

In *automated* crossing networks, resting orders are matched according to a set of rules, without direct interaction between the counterparties. In *negotiated* crossing networks, the counterparties first exchange indications of interest, then negotiate price and size *via* tools provided by the system.

Some traditional exchanges now allow the use of *invisible orders*, resting orders that sit in their order books but are not visible to market participants. These orders are also referred to as *dark liquidity*. The difference between these orders and those placed in a crossing network is that traditional exchanges offer no special antigaming protection.

Private dark pools are collections of orders that are not directly available to the public. For example, a bank or pension manager might have enough order flow to maintain an internal order book that, under special circumstances, is exposed to external scraping by a crossing network or *crossing aggregator*.

A *crossing aggregator* charges a fee for managing a single large order across multiple crossing networks. Order placement and antigaming rules differ across networks, making this task fairly complex. A crossing aggregator may also use information about historical and real-time fills to direct orders. For example, failure to fill a small resting buy order in a crossing network may betray information of a much larger imbalance in the network's book. This makes the network a more attractive destination for future sell orders. In general, the management of information across crossing networks should give crossing aggregators higher fill rates than exposure to any individual network.

Crossing lends itself to several optimization strategies. Longer exposure to a crossing network not only

increases the chances of an impact-free fill, but also increases the risk of a large and compressed execution if an order fails to obtain a fill. Finding an optimal exposure time is one type of crossing optimization. A more sophisticated version of this approach is solving for a *trade-out*, a schedule for trading shares out of the crossing network into the open markets. As time passes and a cross is not obtained, the strategy mitigates the risk of a large, compressed execution by slowly trading parts of the order into the open markets.

Other Algorithms

Two other algorithms are typically included in the mix of standard algorithmic trading offerings. The first is *liquidity seeking* where the objective is to soak up available liquidity. As the order book is depleted, trading slows down. As the order book is replenished, trading speeds up.

The second algorithm is *financed trading*. The idea behind this strategy is to use a sale to finance the purchase of a buy with the objective of obtaining some form of hedge. This problem has all of the components of a full optimization. For example, if, after a sell, a buy is executed too quickly, it will obtain a less favorable fill price. On the other hand, executing a buy *leg* too slowly increases the tracking error between the two components of the hedge and increases the dispersion of costs required to complete the hedge.

What is Next?

The average trade size for IBM, as reported in the Trade and Quote (TAQ) database, declined from 650 shares in 2004 to 240 shares in 2007. Falling trade sizes are evidence of the impact of algorithmic trading. Large, infrequent portfolio rebalancing and trading are being replaced by *small delta continuous trading*.

The antithesis of the small delta continuous trading approach is embodied in the idea of *lazy portfolios*, in which portfolios are rebalanced infrequently to reduce market impact costs. The first argument against lazy portfolios is that as time passes, the weights drift further away from optimal target holdings, in both the alpha and risk dimensions. Second, the use of an optimizer after long holding periods tends to produce large deviations from

current holdings. When executed—often relatively quickly—these deviations result in significant market impact costs.

Engle and Ferstenberg [6] show that to correctly measure risk, we must take both the existing positions and unexecuted shares into account. This idea unites execution risk with portfolio risk. Portfolio construction and optimal execution are similarly united by incorporating market impact costs directly into the portfolio construction process.

Ideally, the portfolio manager would like to solve a problem similar in nature to the multi-period consumption-investment problem [13], that, in addition, takes market impact costs and changing probability distributions for a large universe of securities into account. This *dynamic portfolio* or *small delta continuous trading* problem represents the next step in the evolution of institutional money management. However, it presents some mathematical and computational challenges. As has been pointed out by Sneddon [14], dynamic portfolio problem differs in several important ways from the classical multiperiod consumption-investment problem. First, the return probability distributions change throughout time. Second, the objective functions for active portfolio management do not depend on the predicted alpha/risk, but rather on realized return/risk. Finally, the dynamics of the model may be far more complex. Grinold [7] provides an elegant and analytically tractable but greatly simplified model. Kolm and Maclin [10] describe a full-scale simulation-based framework that incorporates realistic constraints and a transaction cost model.

Other efforts of ongoing research in algorithmic trading are extending market microstructure and optimal execution models to futures, options, and fixed income products. These initiatives follow the dominant theme of algorithmic trading, the creation of a unified view, an all-encompassing framework for the entire trading process, including modeling, portfolio construction, risk analytics, and execution across all tradeable asset classes.

Autocall

An equity-linked autocallable note, or autocall, is a legal instrument in which the notional engaged by the customer is automatically reimbursed when the underlying stock reaches a strike at a specified recalling date or at maturity if such an event does not occur (when the recall appends a coupon is also paid to give the client a return on his/her capital higher than the one he/she would get from an investment in a bond). Equity-linked autocallable notes are examples of hybrid products in the sense that the equity and interest rate movements need to be jointly modeled.

Product Description

A note is a legal wrapper issued by a financial institution. Usually, the capital engaged by the client is guaranteed at maturity and the note also delivers the payoff of a derivative instrument. If T_0 is the issue date, T the maturity, and $B(T_0, T)$, the discount factor between T_0 and T , at T_0 , one unit of the capital guaranteed at maturity is worth $B(T_0, T)$ (if we do not consider the credit risk associated to the issuer). Hence, for an issue at par, the price of the derivative product should be $1 - B(T_0, T)$ (called by practitioner *the available*). Thus, a fixed maturity note can be constructed with any type of payoff as long as the price of the derivative product matches the available.

When buying a note, the goal of the investor is to have a return on his/her capital that is higher than the riskless interest rate one, if the market ends at maturity in his/her expected configuration. However, the problem the client faces with fixed maturity notes is that his/her capital is blocked up until maturity. Autocallable notes solve that issue. The terms of a typical equity-linked autocallable note are listed below:

- At T_0 , the client invests 100.
- The product maturity is T and we consider T_i , $1 \leq i \leq N$ the autocallable dates with $T_0 < T_1 < \dots < T_i < \dots < T_N = T$.
- If S is the underlying (a stock or an index), K_i , $1 \leq i \leq N$ a set of strikes, C_i , $1 \leq i \leq N$ a set of coupon, the payoff is as follows:

- at T_i , $1 \leq i < N$, if the note has not been recalled at a previous autocallable date and if $S_{T_i} \geq K_i$, then the note is terminated (“automatically recalled” in the terminology) and the client receives $100 + C_i$ and,
- at T , if the note has not been recalled at a previous autocallable date and if $S_{T_N} \geq K_N$, the client receives $100 + C_N$; otherwise, he receives 100.

Usually, the autocallable dates have a fixed frequency, the strikes are equal, and the coupons have a linear progression: $C_i = iC$ with C that is higher than the riskless interest rate on the interval $\Delta T = T_{i+1} - T_i$, $0 \leq i < N$. Thus, in a bullish market, the investor can have a higher return on his/her capital than the interest rate one and his/her capital is available as soon as his/her target is reached. This explains why autocallable notes are very popular in the equity markets and have been massively traded in the past years.

Adapted Equity Rate Modeling

Compared to fixed maturity note, the modeling challenge with autocallable notes is the uncertain maturity of the product. With fixed maturity notes, the natural way of hedging the guaranteed capital is to trade a LIBOR-linked interest rate swap (see **LIBOR Rate**) from T_0 to T , where the seller of the note receives the fixed leg (the value of the LIBOR leg is $1 - B(T_0, T)$) and offset the interest rate risk on the capital). With an autocallable note, we can trade the same swap but we need to be able to cancel the remaining part of it at any callable date T_i if $S_{T_i} \geq K_i$. In a deterministic interest rate framework, the hedge would be to wait for the callable date to trade the corresponding remaining swap. Obviously, because the evolution of the interest rates is also a risk factor, this is not acceptable. A joint model on the equity and on the interest rate is required.

Regarding the specific interest rate volatility risk, it is a first-order risk in a sense that an autocallable product is affected by the global level of the rate curve much more than it is by the shape of the distribution of forward start swaps or by the autocorrelation of the rate curve. In other words, a one-factor model on the rate curve is sufficient and a natural choice is an extended Vasicek model (see **Term**

Structure Models) whose term structure of volatility has to be calibrated on the set of swaptions of maturity T_i written on the swap from T_i to T for all $i, 1 \leq i < N$, to be consistent with the autocallable note definition. This calibration set is a very classical one and is usually referred to as the *coterminal calibration set* (for the sum of the maturity of the swaptions and of the length of the corresponding swap is constantly equal to $T - T_0$). Technically, this calibration can be done prior to the equity calibration as it is just associated to the dates of the contract (and possibly to its set of strikes if one wishes to chose swaption strikes not equal to the “at money” strike to integrate a part of the swaption smile risk).

Regarding the equity, we propose a simple representation using only a term structure of volatility to show the impact of the rate factor on the equity volatility. Specifically, we use a two-factor Brownian model, one factor for the interest rate and the other for the Equity. Moreover, we suppose that the Equity is not paying dividends (*see Dividend Modeling*) and that the repo rate (*see Swaps*) is null. Under the risk neutral measure Q , this can be written as

$$\frac{dB(t, T)}{B(t, T)} = r_t dt + \Gamma(t, T) dW_t^{Q,r} \quad (1)$$

$$\frac{dS_t}{S_t} = r_t dt + \sigma_t^S dW_t^{Q,S} \quad (2)$$

$$d\langle W^r, W^S \rangle_t = \rho dt \quad (3)$$

The last equation does not depend on Q as change of measures affects neither the correlation between the Brownian motions nor their volatilities. Moreover, for the first equation, we suppose that the volatility $\Gamma(t, T)$ has been calibrated according to the coterminal calibration set of the product. Since the equity is not paying fixed, discrete dividends, its forward $F(t, T)$ is a martingale under the forward neutral measure Q_T , which is defined as

$$\frac{dQ_T}{dQ}(T) = \frac{\exp\left(-\int_{T_0}^T r_s ds\right)}{B(T_0, T)} \quad (4)$$

The expression of the forward, in that case, is $F(t, T) = S_t/B(t, T)$; hence, we have

$$\frac{dF(t, T)}{F(t, T)} = \sigma^S(t, T) dW_t^{Q_T,S} \quad (5)$$

and also, by combining equations (1) and (2)

$$\frac{dF(t, T)}{F(t, T)} = \sigma_t^S dW_t^{Q_T,S} - \Gamma(t, T) dW_t^{Q_T,r} \quad (6)$$

Hence,

$$\begin{aligned} \int_0^T |\sigma^S(t, T)|^2 dt &= \int_0^T |\sigma_t^S|^2 dt + \int_0^T |\Gamma(t, T)|^2 dt \\ &\quad - 2\rho \int_0^T |\sigma_t^S| |\Gamma(t, T)| dt \end{aligned} \quad (7)$$

Moreover, we have

$$\begin{aligned} E_t^Q[B(t, T)(S_T - K)^+] \\ &= E_t^Q[B(t, T)(F(T, T) - K)^+] \\ &= B(t, T) E_t^{Q_T}[(F(T, T) - K)^+] \end{aligned} \quad (8)$$

which leads to the generalization of the Black and Scholes formula in the sense that, in a setting with stochastic interest rates, the implied volatility Σ_T of the Black and Scholes framework is given by

$$\Sigma_T = \sqrt{\frac{1}{T} \int_0^T |\sigma^S(t, T)|^2 dt} \quad (9)$$

Thus, since the interest rate model has been calibrated independently to the equity model and supposing that the term structure of implied volatility is observed, it is possible to calibrate the term structure of the volatility of the stock, σ_t^S .

From the relation on the volatilities of this simple framework, it is important to note that, depending on the sign of the correlation of the rate factor with the equity factor and of the value of the volatility of the bond, the stock volatility can be either higher or lower than the implied volatility. This does not affect the probability of recalling the note at the first recalling date (which is not conditional) but the probability of recalling the note at a further recalling date conditionally of not having recalled the note at a prior recalling date. Furthermore, the addition of a rate factor, by extending the dimension of the model, leads to a Vega hedging of larger dimension since the swaptions used in the interest rate calibration set should now be considered as hedging instruments, and to a more complex Gamma hedging (*see Gamma Hedging*). In particular, for the latter, the “cross Gamma”, the second derivative with respect to the spot of the equity and to the spot of

the rate, cannot be hedged by any liquid instrument in the market. Therefore, it is necessary to adopt an approach by robustness, applying the same stochastic control arguments as for uncertain volatility models (see **Uncertain Volatility Model**), in order to control the evolution of the value of the hedged portfolio including the autocallable note. Practically, this can be done by replacing the instantaneous correlation between the two factors by an estimation of its upper bound as the cross Gamma, in the case of the autocallable note, is positive.

Advanced Modeling

While the equity/rate issue is truly the specificity of autocallable notes, two other specificities of the equity market need to be taken into consideration for such products, namely, the smile modeling and the dividends.

Regarding the smile issue, the difference between the price of an up binary option in the Black and Scholes framework with a fixed volatility and the price of the same up binary option in the presence of a smile is equal to the Vega of the call of same strike time the opposite of the local skew, $\partial\Sigma/\partial K$, of the implied volatility (this result is a direct application of the fact that an up binary option is bounded by two call spreads). Hence, in the equity market, the presence of a skew increases the price of the up binary option. Applying this result to the autocallable note means that the probability of recalling the note at the closest recalling date is higher if the volatility skew is considered than it is in a setting like the one we proposed earlier and, as a consequence, the term structure of the rate sensitivity is affected. However, while the risk associated to the skew of volatility is therefore important to model, the calibration of a two-factor model including this risk is more complex than what we proposed in the previous part and requires the use of numerical tools such as PDE resolutions (see **Forward-Backward Stochastic Differential Equations (SDEs); Partial Differential Equations; Finite Element Methods**). In particular, it is not possible to use the local volatility formula (see **Local Volatility Model**) as it is specific to a monofactor model.

The dividend risk is not so much of an issue in the case of the autocallable note defined in the section Product Description. However, it could become more

important in structures where the customer chose to risk a loss on his capital by selling a Down and In Put in exchange of higher coupons in case of an early termination. Nevertheless, under the forward neutral measure Q_T , all assets of the form $x_t/B(t, T)$, with x_t a spot process, are martingales (we have used this result in the previous part where S_t is a spot process). Yet, with the addition of fixed discrete dividends, the forward of the equity is including discount factor terms from each dividend dates to the considered maturity. Hence, it is no longer a martingale and, in the presence of stochastic interest rates, the calibration of its volatility is more complex than what we have proposed earlier and also requires the use of advanced numerical tools because of the **Convexity Adjustments** due to the fixed dividends.

Extensions

The payoff we have presented is the most basic one. To increase the value of the coupons, a common practice is to consider a basket of stocks as underlying and to condition the recall on the spot of the worst performer at each recalling date. While this does not change the analysis we have made, this extends the dimension of the problem and can require the integration of other sources of risk such as the equity correlation skew (see **Basket Options**). Moreover, if the stocks are not in the same economy, the number of rate factors also increases and, as explained in **Quanto Options**, quanto drift terms lead to more complex equations.

Another classical extension of the autocallable note is to condition the coupon on a rate instrument. Typically, upon recall, the coupon paid would be equal to a swap rate or a LIBOR rate plus a fixed spread. In that case, it is usually necessary to adapt the rate factor to have correct convexity adjustments (see **CMS Spread Products** for the explanation of the convexity adjustment for constant maturity swaps and **Bermudan Swaptions and Callable Libor Exotics** for correlated issues). Moreover, in that case, the impact of the joint equity/rate modeling on the price of the autocallable note is far more important than it is in the fixed coupons case.

There are a few more extensions of the autocallable note that have been proposed in the recent

years, but the payoffs we have mentioned represent the vast majority of traded contracts. Yet, in all cases, the modeling challenge lies in the integration of stochastic interest rates in the equity

framework, which defines autocallable notes as hybrid products.

CHARLES-HENRI ROUBINET

Municipal Bonds

Municipal bonds are bonds issued by local and state governments to raise funds for public works with interest payment(s) that are generally exempt from federal taxes, and often from state and local taxes as well. An investor who buys a bond will receive interest payments at a stated yield rate until the bond reaches maturity, at which time the principle, or *par*, will be returned. Not all municipal bonds are tax exempt. Those intended for purposes not essential to the public good, such as those issued to finance sports arenas, for example, are taxable. Typically though, the terms *municipal* and *tax exempt* are synonymous.

There are two main types of municipal bonds: *general obligation* and *revenue*. Both are used to raise funds for public works, but they differ in how they generate the proceeds to service the interest and/or principal payment(s). General obligation bonds use tax revenue to pay back bondholders, while revenue bonds use money generated from the works themselves; a toll road, for instance, would pay the bond interest using monies raised by tolls. Neither is necessarily a more secure investment. General obligation municipal bonds, which tie interest payments to taxes, are rated based on the creditworthiness of their issuers. Since these are local or state governments, they are assessed by comparing the strength of their tax base to their debt service requirements. Revenue bonds, in contrast, are rated based on their *debt service coverage ratio*, which divides the amount of interest to be paid by the amount of money available, as estimated by analysis of past and future data. Moody's, Standard & Poor's, and Fitch Ratings are the large commercial ratings agencies that establish the basis for most assessments of municipal bond ratings.

Revenue bonds generally yield more than general obligation bonds do, though neither is considered risk-free; taxes cannot be raised without limit to pay back general obligation investors during a financial crisis, nor can revenue bonds be guaranteed to always cover their debt service. If a bond's credit quality falls, its yield will increase and its price will drop, which will make it more attractive to investors. Both types can be resold in the secondary market, though not without considerable cost.

Bond insurance, purchased by the issuer to cover both the principal and interest in case of default,

can also be a factor in the rating of particular bond. A bond backed by a bond insurance firm carries the firm's investment rating, though that rating will change if the insuring firm's rating is downgraded. The yields on insured bond are generally somewhat lower than they otherwise would be, but investors have an extra safeguard against the risk of default, which has the ancillary benefit of making these bonds easier to resell in the secondary market. It is important for investors to know what the rating of a particular bond, or bonds of that type, would be if it were uninsured.

Another factor which investors consider when evaluating a municipal bond is its coupon rate, meaning the rate at which it pays interest until it matures. A bond's coupon rate can be fixed or it may be reset periodically; this latter type is referred to as a *floating-rate* or *variable-rate* issue.

Several specialized subsets of municipal bonds exist, with particular revisions to key features. For instance, municipal bonds may be issued as "refunded" bonds, which are backed by US Treasury bonds held in escrow. Municipalities that issued bonds at higher interest rates in the past can issue new bonds, "refunded bonds," at lower rates to redeem the principal of these older bonds; the proceeds from the sale of the new bonds are used to buy US Treasury securities, which back the coupon payments for the original bonds, freeing them of any default risk. These refunded bonds typically have shorter maturities and corresponding low interest-rate risks. Because their yields are backed by funds held in escrow and are therefore risk-free, these are highly valued bonds, almost always carrying an AAA rating.

Municipal notes are another category of municipal bonds. Municipal notes have maturities less than three years and are issued in anticipation of some future municipal revenue, either from taxes or bonds.

Municipal zeros, another special type of municipal bond, are issued at a discount from their *par* value, which refers to the amount of their principal. When they reach maturity, they are redeemed for their full par value, with the difference between the two rates equaling a specified compounded annual yield. Because municipal zeros pay no interest, potential investors must carefully consider the creditworthiness of their issuers. Issuers also retain a fuller freedom to *call* these bonds, meaning that they can collect these bonds before they mature, at a price discounted from par.

Some municipal bonds are issued with *put* provisions, meaning that purchasers can tender the bond back to the issuer at par, which offers security for investors, though not without trade-offs. The total return on these bonds is usually lower, and in the case that interest rates decline, they will appreciate less than comparable long-term bonds.

Many other specialized types of municipal bonds attract different investors. *Dedicated tax-backed bonds* or *structure/asset bonds* meet their debt service with certain revenues, such as sales taxes, dedicated to repayment of the debt. Other types include *letter of credit back bonds*, *moral obligation bonds*, and *tax-allocation bonds*.

Several aspects influence municipal bond pricing. Municipal bonds can be priced at a discount, at par, or at premium. The bond's features, including its maturity, call features, and credit quality, influence its price. A *call risk* refers to the possibility that the issuer will redeem a bond before its maturity date, meaning that purchasers will not earn the subsequent interest. Issuers typically may redeem bonds at stipulated dates, starting at 10 years from the date of issue, and at 5-year intervals thereafter, at prices increasing from par, though housing bonds can have more irregular call features. A substantial drop in interest rates may cause an issuer to call a municipal bond.

Municipal bond pricing can vary because of the disparities between broker markups and the general lack of transparency in the pricing process. In general, smaller lots, those with values less than \$25 000, are more difficult to sell and so are marked up disproportionately by brokers, and their prices can be unpredictable. Larger lots generally sell at narrower price ranges. Other price factors include whether the bond is well known and widely traded, and whether it is insured. Much of the price information available though still applies generally to very large lots, purchased wholesale by institutions, not by individual investors.

Municipal bonds can be bought from brokerage firms, both full service and discount, including those who specialize in municipal bonds, in addition to banks. All of these offer online-purchasing options, though generally with both markups and "transaction fees" added on. Buying bonds as they first become available is known as *buying at issue*, which has several attractive features. During this short time, bonds are sold at a uniform price, often at par, and

dealers anxious to sell will offer good prices, which results in attractive yields.

While buying municipal bonds, it must be borne in mind that a key distinction exists between premium and discount bonds. Premium bonds yield more than discount bonds, assuming an equality of credit quality and maturity, because their yield to maturity, the amount they will earn with interest over their lifespan, will be equal to their actual yields. In contrast, discount bonds have yields, which include a taxable capital gain because they are sold at prices below their maturity value. Only coupon interest is exempt from federal taxes, which lowers discount bonds' actual yield below their quoted yield to maturity. Premium bonds have a higher coupon value, meaning that they produce more interest income, making them better suited to investors who want their short-term municipal bond holdings to yield an income to reinvest. Others looking to hold onto their bonds to maturity and use them to fund long-term investments will be better served by discount bonds.

While municipal bonds are generally free from federal taxes, which is their most attractive feature, state or local taxes may still apply. Out-of-state buyers may be exempt from these taxes. Other tax considerations include the alternative minimum tax, which applies to bonds for "nonessential" projects issued after August 7, 1986, but typically only for buyers with large incomes. This is also true of *de minimus* taxes, which applies to discount bonds. Taxability of a bond at the local, state, or federal level is not the only criterion to determine its potential value to an investor; depending on which tax bracket the investor is subject to, a taxable bond may still offer a higher yield.

Municipal Bond Arbitrage

In recent years, many bond traders, investment banks, and hedge funds have created leveraged bond portfolios that utilize what we may call municipal bond arbitrage strategies. The origin of municipal arbitrage is the generally cheaper pricing of long maturity municipal bonds relative to similar fixed income investments. There are two approaches: those that use tender option bond programs to augment the yield spread earned by hedging municipal carry trades, and those that use basis trading strategies to exploit volatility in the relative value of municipals. Both

types of arbitrage impact the municipal market as a whole by increasing liquidity and improving price discovery.

Municipal arbitrage is similar to other types of fixed income arbitrage; it targets pricing inefficiency, hedges against the fluctuation of interest rates, and uses leverage. However, unlike its now infamous cousin, mortgage-backed security arbitrage, opportunities in municipal arbitrage, though not without their own risks, arise from the inherent structure of the municipal market, rather than from the sheer complexity of modeling risk in that market.

The Structure of Municipal Bond Arbitrage Strategy

Municipal bond arbitrage trades are typically hedged against interest rates with LIBOR swaps [2]. The trader makes a semiannual fixed payment at a market rate set at the time of the swap, and receives a variable payment set at the quarterly LIBOR reference rate. As interest rates fluctuate, so does the swap's value.

The price value of a basis point is calculated by comparing a one basis point change in interest rates across the yield curve to the corresponding change in the value of an interest-hedged position. This is also known as the *swap's dollar duration*. The hedge ratio is the ratio of the dollar durations of the swap position and the original bond position.

As his/her starting point is a municipal carry trade, the trader also seeks to generate income by locking in the municipal yield premium; when financing and hedging costs are subtracted from this is, it is known as the *net spread*. The municipal *versus* LIBOR yield ratio is thus a supplementary source of profit or loss.

Hedging

The basis of a hedged position is the difference in value between the hedge and the security that is hedged by it. The greater their dissimilarity, the greater the basis risk—in other words, the risk that the hedge position will diverge in value from the hedged position. The arbitrageur attempts to isolate the basis risk of a dubiously priced security by hedging against other risks, as in the interest-rate swaps previously described. Yield curve risk can be hedged by taking a bond position of the same tenor.

Tax risk, issuer default risk, and liquidity risk should also be considered, though they are simply considered part of the basis in calculating the municipal/LIBOR yield ratio.

The arbitrageur must also determine a suitable hedging ratio once the hedge itself is chosen. This is typically done by balancing the dollar durations of one basis point of the bond and one basis point of the hedge. At the same time, the arbitrageur proceeds under the assumptions that the yield on the bond and the yield on the hedge will not remain symmetrical and that this yield ratio itself is influenced by interest-rate changes. What the arbitrageur must attempt to anticipate is the hedge beta, or the change in municipal yields that accompanies any change in taxable yields. Traders use several methods to estimate hedge beta. Ratio-based hedges use the yield ratio itself, supposing that it will revert to a mean or to the overall market. Regression-based hedges differ in that they account for the usual inverse correlation between yield ratios and interest rates. Alternately, some traders consider the interest-rate variance as the key component of the position and hedge accordingly. It is also possible to hedge against the callability of longer municipal bonds (which is typically priced into quoted yields).

Tender Option Bonds, Variable-rate Demand Obligations, and Leverage

Most municipal bond arbitrage strategies incorporate leverage, which is enabled by tender option bond programs (TOBs) that securitize bonds or bond portfolios and thus allow them to be financed at what amounts to tax-exempt rates [1]. Leverage is achieved in the taxable bond market by means of repurchase transactions, in which the owner of a security sells it to a second party while agreeing to repurchase it later at a higher price. If a lender provides similar means to purchase a municipal bond, the interest he receives will still be fully taxable. However, borrowers cannot deduct this interest cost, since they are purchasing a tax-exempt security. As a result, borrowers will generally receive a lower yield from the lender even though they are financing at a higher rate.

In order to finance the municipal bond purchase, the tender option bond trusts can separate the bond into a tax-efficient component and a second component that is exposed to tax risk (along with liquidity

risk and the other risks that account for its yield curve premium) by creating the following:

1. A short-term, variable-rate instrument backed by a long-term municipal bond.
2. An instrument that passes the upside and downside of this collateral to an investor who seeks leveraged exposure to a municipal bond.

Tender option bond programs are sponsored by most major municipal bond dealers. All of these programs allow customers to structure leveraged municipal bond position by issuing short-term money-market securities collateralized by long-term municipal bonds (sometimes called *floaters*) in tandem with securities that represent a leveraged position in the collateral (sometimes called *residuals*).

The fate of the underlying bonds is largely determined by the residual holders, who generally hold the right to require the floater holders to tender their securities with a 1-day notice, allowing the former to terminate the trust and liquidate the underlying bonds. Floaters have priority access to payments from the trust, which allows them to take advantage of a rise in short-term rates (leaving, perhaps, little income to the residuals).

As with variable-rate demand obligations (VRDOs), the rate on the floaters is set by the remarketing agent at a level that allows the bond to be remarketed at par. When the underlying bonds are deposited, the trust becomes the legal owner. The trustee administers the trust and its payments on behalf of the beneficial owners, that is, the holders of the floaters and the residuals. TOBs are tax partnerships in order to preserve the underlying bonds as tax exempt, which means that there are specific guidelines that govern gain sharing and termination and tend to discourage active trading of the underlying bonds. Both types of tender option bond securities are only available as private placements.

Some companies are able to efficiently finance municipal bonds without TOBs; the tax code stipulates that interest costs are deductible if tax-exempt obligations are less than 2% of the taxpayer's assets. (Municipal bond broker-dealers can deduct interest costs in this manner by classifying a portion of their inventory as equity-funded rather than as debt-funded).

Furthermore, some tender option bond programs offer pooled trusts to increase leverage, new tools for hedging such as credit default swaps are available, and nontraditional participants (e.g., foreign taxpayers) are entering the market through municipal ratio swaps. Even market participants who do not use arbitrage strategies should be aware of these developments because of their potential to impact the shape of the market as a whole.

Asset–Liability Management

Asset–liability management is a major concern for large financial institutions. Assets must be invested to achieve sufficient returns to pay liabilities and achieve goals subject to uncertainties, policy, taxes, and legal constraints. This article discusses asset and liability management with portfolio complexities, transaction costs, liquidity, taxes, investor preferences (including downside risk control, policy constraints, and other constraints), uncertain returns, and the timing of returns and commitments. Applications to the management of investment portfolios for large financial institutions, including pension funds and insurance companies, and for individual life-cycle planning are discussed. The approach recommended is discrete-time, multiperiod stochastic programming. For most practical purposes, such models provide a superior alternative to other approaches, such as mean–variance, simulation, control theory, and continuous-time finance. These models utilize investor preferences in a simple, understandable way. We present the Russell–Yasuda Kasai and the InnoALM models, both of which had a major impact on the practice of asset–liability management (ALM).

The use of scenario-based, stochastic programming optimization models in discrete time provides an approach to asset–liability modeling over time. The models provide a tool to think about, organize, and do calculations concerning how one should choose asset mixes over time to achieve goals and cover liabilities. Risk and return are balanced to achieve period-by-period goals and pay liabilities. The models force diversification and the consideration of extreme scenarios to protect investors from the effects of tail outcomes and also do well in normal times. They will not let individuals or institutions get into situations in which extreme, but plausible, scenarios would lead to truly disastrous consequences, such as losing half or more of one’s assets. Because these models force consideration of all relevant scenarios, the common practice of assuming that low-probability scenarios will not occur is avoided. Hence, the disasters that frequently follow from this error are avoided.

In discrete-time, multiperiod stochastic programming models, one typically maximizes a concave,

risk-averse utility function composed of the discounted expected wealth in the final period less a risk measure composed of a risk-aversion index times the sum of convex penalties for target violations relating to investor goals of various types in various periods. The convexity means that the larger the target violation, the larger the penalty cost. Hence, risk is measured as the nonattainment of investor goals, and this risk is traded off against expected returns. This approach is similar to a mean–variance preference structure, except that it is based on final wealth and the risks are downside risks that are measured across periods and investor goals. Discrete scenarios that represent the possible returns and other random parameter outcomes in various periods are generated from econometric and other models, such as those related to market dangers with increasing risk and from expert modeling. Mean-return estimation and the inclusion of extreme events are important for model success. The scenario approach has a number of advantages:

- Normality or lognormality, which is not an accurate representation of actual asset prices (*see Stylized Properties of Asset Returns; Heavy Tails*), especially for losses, need not be assumed.
- Tail events can be easily included; studies show that downside probabilities estimated from actual option prices are 10–1000 times fatter than log-normal (*see Heavy Tails; Stylized Properties of Asset Returns*).
- Scenario-dependent correlations between assets can be modeled and used in the decision-making process so that “normal” and “crisis” economic times (with higher and differing signed correlations) can be considered separately.
- The exact scenario that will occur and the probabilities and values of all the scenarios need not be accurately determined to provide model performance that is superior to that of other models and strategies, such as mean–variance or portfolio insurance.
- Most of the natural, practical aspects of asset–liability applications can be modeled well in the multiperiod stochastic programming approach. Model output is easy to understand by nonexperts such as pension fund trustees. The models can be tested *via* simulation and statistical methods and considerable independent evidence

demonstrates their superiority to other standard approaches and strategies.

- The approach protects investors from large market losses by considering the effects of extreme scenarios while accounting for other key aspects of the problem.
- Determining whether investment positions are truly diversified and of the right size across time is crucial to protect against extreme scenarios and ensure that the results will be good in normal times and avoid disasters.

Procedures for Scenario Generation

There are many methods to estimate scenarios. Abaffy *et al.* [1, 10] survey scenario estimation and aggregation methods that represent a larger number of scenarios by a smaller number. See [31] for further references and discussion. Scenarios are a means to describe and approximate possible future economic environments. They are represented as discrete probabilities of specific events. Together, all the scenarios represent the possible evolution of the future world. The basic idea is to have a set of T period scenarios of the form $S^T = (S_1, S_2, \dots, S_T)$, where $s_t \in S_t$ are the possible outcomes of all random problem elements and where s_t occurs in period t with probability $p_t(s_t)$.

For asset–liability modeling, the most important parts of the distribution are the means and the left tail. The mean drives the returns and the left tail the losses. We cannot include all possible scenarios but rather focus on a discrete set that well approximates the possible important events that could happen. With S^T total scenarios, we can include those we want. Once a scenario is included, the problem must react to what would be the consequences of that scenario. This important and flexible feature of stochastic programming modeling is not usually available in other approaches. The inclusion of such extreme scenarios means that the model must react to the possibility of that scenario occurring. This inclusion is one of the ways a stochastic programming overall model would have helped mitigate the 1998 losses and collapse of LTCM (see **Long-Term Capital Management**). The model would not have let them hold such large positions. We frequently aggregate scenarios to pick the best N out of the S^T so that the modeling effort is manageable. The generation of good scenarios that well represent the future

evolution of the key parameters is crucial to the success of the modeling effort.

Among other things, scenarios should consider the following:

- mean reversion of asset prices;
- volatility clumping, in which a period of high volatility is followed by another period of high volatility;
- volatility increases when prices fall and decreases when they rise;
- trending of currency, interest rates, and bond prices;
- ways to estimate mean returns;
- ways to estimate fat tails; and
- ways to eliminate arbitrage opportunities or minimize their effects.

The true distribution P is approximated by a finite number of points $(w^1, \dots, w^S)$ with positive probability p^s for each scenario s . The sum of all scenario probabilities is 1.

Economic variables and actuarial predictions drive the liability side, whereas economic variables and sentiment drive financial markets and security prices. Hence, estimating scenarios for liabilities may be easier than for assets because there often are mortality tables, actuarial risks, legal requirements, such as pension or social security rules, well-established policies, and so on. Such scenarios may come from simulation models embedded into the optimization models that attempt to model the complex interaction between the economy, financial markets, and liability values. We can use the following classification:

1. There can be complete knowledge of the exact probability distribution. This knowledge usually comes from a theoretical model, but it is possible to use historical data or an expert's experience.
2. There can be a known parametric family based on a theoretical model whose parameters are estimated from available and possibly forecasted data.
3. Scenarios can be formed by sample-moment information that aggregates large numbers of scenarios into a smaller, easier set or generates scenarios from assumed probability distributions. This idea was used in the five-period Russell–Yasuda Kasai insurance model in 1989 [6]. Høyland and Wallace (HW) [17] have expanded and refined the idea for multiperiod

problems and they have generated scenarios that match some moments of the true distribution. Typically it is the first four moments.

4. The idea is to assume that the past will repeat in the sense that events that occurred with various probabilities will reoccur with the same probabilities but not necessarily in the same order. Despite missing fat tails, the method has had some success. This idea can be implemented by using the raw data or through procedures, such as vector autoregressive modeling or bootstrapping, that sample from the past data. Using subsets of past data is a viable scenario generation method. Grauer and Hakansson [13] have successfully used the idea in many asset-only studies. When no reliable data exist, one can use an expert's forecasts. Examples include [24, 28] or governmental regulations.
5. The Hochreiter and Pflug (HP) [16] approach generates scenario trees using a multidimensional facility location problem that minimizes a Wasserstein distance measure from the true distribution. Kolmogorov–Smirnov (KS) distance approximation is an alternative approach, but it does not take care of tails and higher moments. The HP method combines a good approximation of the moments and the tails.

Whatever method is used to generate the scenarios, in relying on the meshing of decision-maker subjective estimates, expert judgment, and empirical estimation, it is crucial to validate the estimated distributions and to make sure that the decision maker has not defined the range too narrowly. Perhaps reflecting on the distribution by asking what would make the value be outside the range and then assessing the probability would help expand the range and make the probability assessment more realistic.

Assessing Scenarios

The philosophy proposed here for assessing scenarios is as follows. Markets are understandable most (over 95%) of the time, but real asset prices have fat tails because extreme events occur much more frequently than lognormal or normal distributions indicate. According to Keim and Ziemba [20], much of asset returns are *not* predictable. Hence, we must have ways to combine conventional models, options pricing, and so on, which are accurate most of the

time with the irrational unexplainable aspects that occur once in a while. Whether the extreme events are predictable is not the key issue—what is *crucial* is that we consider that they can happen in various levels with various chances.

Even apart from the instability due to speculation, there is the instability due to the characteristic of human nature that a large proportion of our positive activities depend on spontaneous optimism rather than mathematical expectations, whether moral or hedonistic or economic. Most, probably, of our decision to do something positive, the full consequences of which will be drawn out over many days to come, can only be taken as the result of animal spirits, a spontaneous urge to action rather than inaction, and not as the outcome of a weighted average of quantitative benefits multiplied by quantitative probabilities [21].

Human behavior is a main factor in how markets act. Indeed, sometimes markets act quickly, violently with little warning. Ultimately, history tells us that there will be a correction of some significant dimension. I have no doubt that human nature being what it is, that it is going to happen again and again [14].

As a working background hypothesis, we assume that markets are basically efficient most of the time, so we have to deal with that plus the anomaly and behavioral finance departures from efficiency.

Dynamic and Liability Aspects

Figure 1 shows the time flow of assets arriving and liability commitments leaving for institutions, such as insurance companies, pension funds, banks, and individuals.

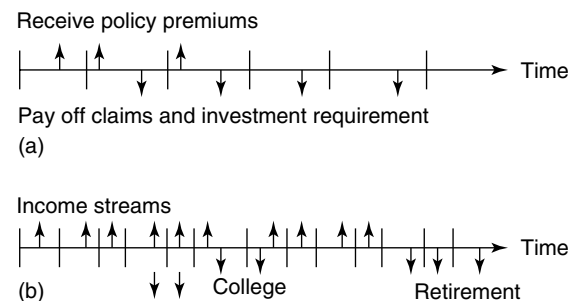

Figure 1 Time flow of assets: (a) institutions and (b) individuals

Ziemba and Mulvey [32] suggest the following risk ladder with various levels of details, aggregation, and model decisions.

- *Rung 5*: Total integrated risk management.
- *Rung 4*: Dynamic asset and liability management.
- *Rung 3*: Dynamic asset-only.
- *Rung 2*: Static asset-only portfolios.
- *Rung 1*: Pricing single securities.

This article concerns mostly Rung 3 and, especially, Rung 4. Rung 5 represents overall company-wide models that involve all aspects of a business; see [26].

The stochastic programming approach, which considers the following aspects, is ideally suited to analyze such problems. It is argued that it has the following elements.

- Multiple time periods; possible use of end effects—steady state after decision horizon adds one more decision period to the model; the trade-off is to have either an end-effects period or a larger model with one less period. The Russell–Yasuda Kansai model uses end effects while the InnoALM model does not.
- The scenarios should be consistent with economic and financial theory for asset returns, interest rates, and bond prices with anomaly and behavioral finance scenarios included.
- Discrete scenarios for random elements—returns, liabilities, and currencies.
- Scenario-dependent correlation matrices so that correlations change for extreme scenarios. This was first implemented in the InnoALM model. Since bond prices rise during stock market crashes, these assets are negatively correlated then but they are positively correlated otherwise. Thus, capturing this effect with one correlation matrix will not work. One simply needs multiple correlation matrices for scenarios sets. The LTCM and October 27–28, 1997 crash examples discussed in [31] remind one of the importance of this.
- The use of various forecasting models that can handle fat tails.
- Institutional, legal, and policy constraints.
- Model derivatives and illiquid assets.
- Model the transaction costs.
- Use expressions of risk in terms understandable to decision makers item.

- Simple, easy-to-understand concave, piecewise linear, risk-averse utility functions that maximize long-run expected profits, net of expected discounted penalty costs for shortfalls, are suggested. One pays more penalty for shortfalls as they increase (highly preferable to Value-at-Risk (VaR)).
- Model as constraints or penalty costs for target violations in the objective function. This allows for multiple goals through targets within periods and across periods. However, one must be able to specify the relative importance of these targets within periods and across periods.
- Adequate reserves, cash levels, and regularity requirements must be maintained.
- Realistic multiperiod problems can now be solved on modern workstations and personal computers by using large-scale linear programming and stochastic programming algorithms.
- The model makes one diversify—the key for keeping out of trouble.

Some possible approaches to model situations with such events are as follows:

- Simulation models have very large output to understand but are very useful as a check. Stochastic programming (SP) models are useful because they can easily perform stress tests and what if calculations.
- Mean–variance models are static in nature and useful for such applications, but they are not very useful with liquidity or other constraints or for multiperiod problems or with liabilities, and so on.
- Expected log models yield very risky short-term strategies that do not diversify well; fractional Kelly with downside constraints is excellent for risky investment betting [23, 30].
- Many stochastic control models, although theoretically interesting, give hair-trigger and bang-bang policies in which one is 100% stocks and then 0% stocks one second later (*see Stochastic Control; Uncertain Volatility Model*). See, for example, the Brennan and Schwartz model [3] in [32] and the Rudolf and Ziemba model [27]. The question is how to constrain the asset weight changes to be practical. Possibly, the best work with this approach has been done by Campbell and Viceira [4], who used the approach successfully to analyze long-term asset-only allocation decisions in

which the power of the technique dominates the limitations of the model (which they acknowledge). Among other conclusions, they show the following:

1. The riskless asset for a long-term investor is not Treasury-bills; rather, it is an inflation-indexed bond since it delivers a predictable stream of real income.
2. A safe labor income stream is equivalent to a large position in the risk-free asset, allowing the investor to hold much more in risky assets; then, this is reversed to some extent. Fixed commitments are negative income.
3. Risky investments are extremely attractive to young households because they have large relatively safe human wealth relative to their financial wealth.
4. Business owners should have less equity exposure since their income stream is correlated with the stock market.
5. Wealthy investors should be more risk averse since more of their consumption stream depends on their financial success.
6. Since stocks are mean reverting, that is, they have lower risk over longer time horizons, investors can time the market over longer horizons; since the equity risk premium is time varying, the optimal strategic allocation mix changes over time. These are useful rules of thumb for many investors derived from a theoretically sound framework. The goal in SP-ALM models is to tailor the asset-allocation mix for the particular institution or investor given their consumption and other goals, taxes, preferences, uncertainties, transactions costs, liquidity, and so on.
7. Stochastic programming models with decision rules have policy prescriptions, such as fixed mix or buy and hold; the decision rules are intuitively appealing but are suboptimal and usually lead to nonconvex difficult optimization modeling.

Stochastic Programming is Superior to Fixed Mix

Despite their good results, fixed-mix and buy-and-hold strategies do not use new information from return outcomes in their asset allocation (see **Fixed Mix Strategy**). Indeed, their asset allocation is fixed

independent of all new information. Hence, a stochastic programming model that reacts to such information should be superior. For an example of this, see [31].

Fleten *et al.* [11] compared two versions, namely, multistage stochastic linear programming and fixed-mix, of a portfolio model for the Norwegian life insurance company Gjensidige NOR. They found that the multiperiod stochastic programming model dominated the fixed-mix approach. However, the degree of dominance was much smaller out of sample than in sample (Figure 2).

Why does the SP advantage decrease so much? The answer seems to be that out of sample, the random input data are structurally different from those in sample, so the stochastic programming model

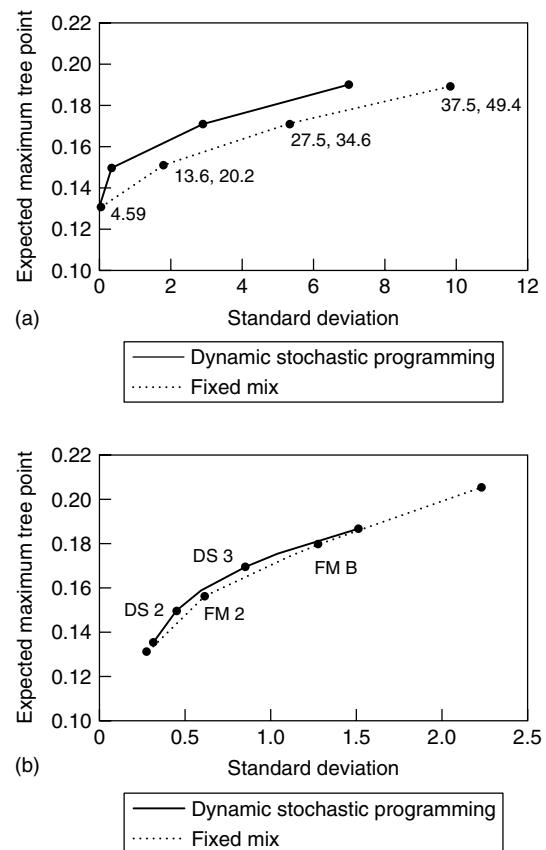

Figure 2 Advantage of stochastic programming over fixed-mix model: (a) in-sample results and (b) out-of-sample results [Reproduced from Fleten *et al.*, 2002. © Elsevier.]

loses its advantage in optimally adapting to the information available in the scenario tree. In addition, the performance of the fixed-mix approach improves because the asset mix is updated at each stage through its volatility pumping procedure.

The Russell–Yasuda Kasai Model

The Russell–Yasuda Kasai model was the first large-scale multiperiod stochastic programming model implemented for a major financial institution (see [15]). The model was designed while the author was working as a consultant to the Frank Russell Company in Tacoma, Washington, from 1989 to 1991. Under the direction of Research Head Andy Turner, the team of David Cariño, Taka Eguchi, David Myers, Celine Stacy, and Mike Sylvanus at Russell in Tacoma, Washington, implemented the model for the Yasuda Fire and Marine Insurance Company in Tokyo.

The Russell–Yasuda Kasai model was designed to satisfy the following need, as articulated by Kunihiro Sasamoto, director and deputy president of Yasuda Kasai:

The liability structure of the property and casualty insurance business has become very complex, and the insurance industry has various restrictions in terms

of asset management. We concluded that existing models, such as Markowitz mean–variance, would not function well and that we needed to develop a new asset–liability management model.

The Russell–Yasuda Kasai model is now at the core of all asset–liability work for the firm. We can define our risks in concrete terms, rather than through an abstract, in business terms, measure like standard deviation. The model has provided an important side benefit by pushing the technology and efficiency of other models in Yasuda forward to complement it. The model has assisted Yasuda in determining when and how human judgment is best used in the asset–liability process ([5], p. 49)

The full model is described in [6, 7]. Figure 3 shows the decision-making process. The Russell–Yasuda Kasai model led to other Russell models (Table 1).

InnoALM: The Innovest Austrian Pension Fund Financial Planning Model

Siemens Oesterreich, a part of the global Siemens Corporation, is the largest privately owned industrial company in Austria. Its businesses, with revenues of €2.4 billion in 1999, include information and communication networks, information and communication products, business services, energy and traveling technology, and medical equipment. Its pension fund,

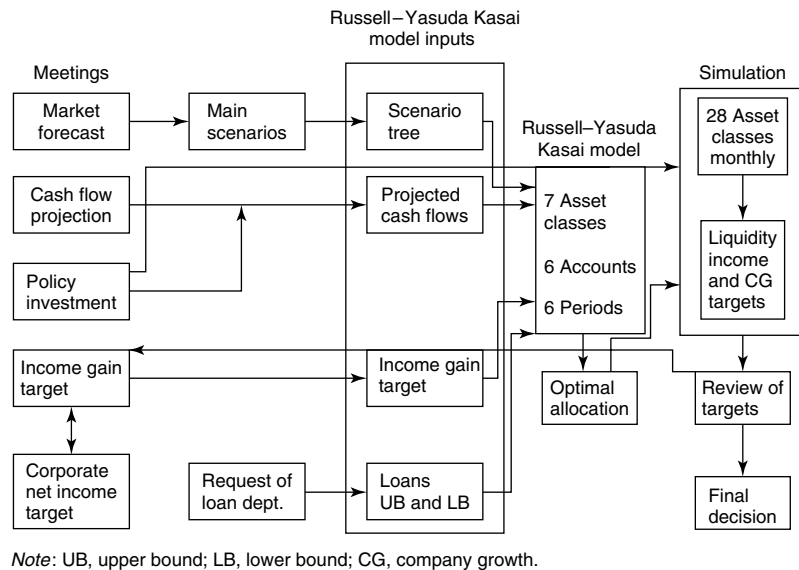

Figure 3 Yasuda Kasai’s asset–liability decision-making process [Reproduced from Cariño, 1994. © INFORMS.]

established in 1998, is the largest corporate pension plan in Austria and is a DCP. More than 15 000 employees and 5000 pensioners are members of the pension plan, which had €510 million in assets under management as of December 1999.

Innovest Finanzdienstleistungs, the investment manager of the Siemens pension plan, was rated as the best plan in Austria. Various uncertain aspects, possible future economic scenarios, stocks, bonds, and other investments, transaction costs, liquidity, currency aspects, liability commitments over time, Austrian pension fund law, and company policy suggested that a good way to approach this asset–liability problem was *via* a multiperiod stochastic linear programming model. This model has innovative features, such as state-dependent correlation matrices, fat-tailed asset-return distributions, simple computational schemes, and output. InnoALM was developed in six months in 2000, with Geyer and Ziemba serving as consultants and with assistance from Herold and Kontriner from Innovest.

The liability side of the Siemens pension plan consists of employees for whom Siemens is contributing DCP payments and retired employees who receive pension payments. Contributions are based on a fixed fraction of salaries, which varies across employees. Active employees are assumed to be in steady state; thus, employees are replaced by a new employee with the same qualification and sex so that there are a constant number of similar employees. Newly employed staff start with less salary than retired staff, which implies that total contributions grow less rapidly than individual salaries.

The set of retired employees is modeled using Austrian mortality and marital tables. Widows receive 60% of the pension payments. Retired employees receive pension payments after reaching age 65

for men and 60 for women. Payments to retired employees are based on the individually accumulated contribution and the fund performance during active employment. The annual pension payments are based on a discount rate of 6% and the remaining life expectancy at the time of retirement. These annuities grow by 1.5% annually to compensate for inflation. Hence, the wealth of the pension fund must grow by 7.5% a year to match liability commitments. Another output of the computations is the expected annual net cash flow of plan contributions minus payments. Because the number of pensioners is rising faster than plan contributions, these cash flows are negative and the plan is declining in size.

The model determines the optimal purchases and sales for each of N assets in each of T planning periods. Typical asset classes used at Innovest are US, Pacific, European, and emerging market equities and US, UK, Japanese, and European bonds. The objective is to maximize the concave risk-averse utility function “expected terminal wealth” less convex penalty costs subject to various linear constraints. The effect of such constraints is evaluated in the examples that follow, including Austria’s limits of 40% maximum in equities, 45% maximum in foreign securities, and 40% minimum in Eurobonds. The convex risk measure is approximated by a piecewise linear function, so the model is a multiperiod stochastic linear program. Typical targets that the model tries to achieve (and is penalized for if it does not) are for growth of 7.5% a year in wealth (the fund’s assets) and for portfolio performance returns to exceed benchmarks. Excess wealth is placed into surplus reserves, and a portion of the excess is paid out in succeeding years.

Table 1 Russell business engineering models

Model	Type of application	Year delivered	Number of scenarios	Computer hardware
Russell–Yasuch (Tokyo)	Property and casualty insurance	1991	256	IBM RISC 6000
Mitsubishi Trust (Tokyo)	Pension consulting	1994	2000	IBM RISC 6000 with parallel processors
Swiss Bank Corp. (Basle)	Pension consulting	1996	8000	IBM UNIX2
Daido Life Insurance Company (Tokyo)	Life insurance	1997	25 600	IBM PC
Banca Fideuram (Rome)	Assets only (personal)	1997	10 000	IBM UNIX2 and PC
Consulting Clients	Assets only (institutional)	1998	Various	IBM UNIX2 and PC

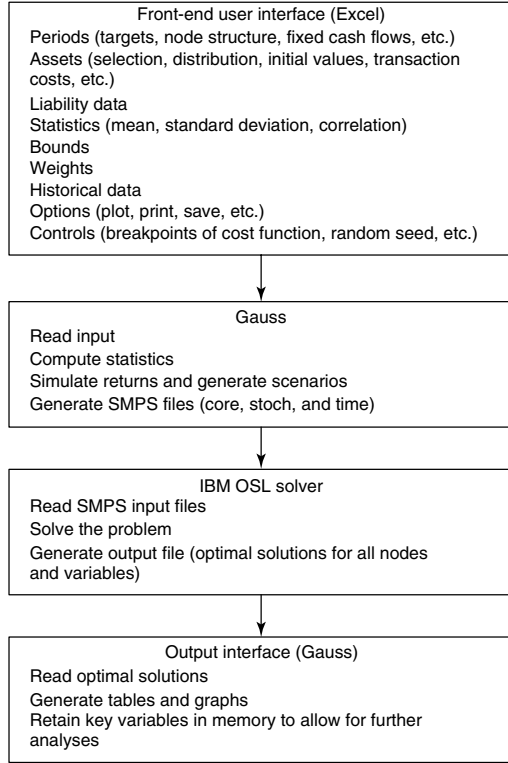

Figure 4 Elements of InnoALM [Reproduced from Geyer and Ziemba, 2008. © INFORMS.]

The elements of InnoALM are described in Figure 4. The interface to read in data and problem elements uses Excel. Statistical calculations use the program Gauss, and these data are fed into the IBM OSL solver, which generates the optimal solution to the stochastic program. The output uses Gauss to generate various tables and graphs and retains key variables in memory to allow for future modeling calculations.

Formulation of InnoALM as a Multistage Stochastic Linear Programming Model

The nonnegative decision variables are wealth (after transactions) W_{it} , and purchases P_{it} and sales S_{it} for each asset ($i = 1, \dots, N$). Purchases and sales are in periods $t = 0, \dots, T - 1$. Purchases and sales are scenario dependent except for $t = 0$.

Wealth accumulates over time for a T period model according to

$$W_{i0} = W_i^{\text{init}} + P_{i0} - S_{i0}, \quad t = 0 \quad (1)$$

$$\tilde{W}_{i1} = \tilde{R}_{i1} W_{i0} + \tilde{P}_{i1} - \tilde{S}_{i1}, \quad t = 1 \quad (2)$$

$$\tilde{W}_{it} = \tilde{R}_{it} \tilde{W}_{i,t-1} + \tilde{P}_{it} - \tilde{S}_{it}, \quad t = 2, \dots, T - 1 \quad (3)$$

and

$$\tilde{W}_{iT} = \tilde{R}_{iT} \tilde{W}_{i,T-1}, \quad t = T \quad (4)$$

where W_i^{init} is the prespecified initial value of asset i . There is no uncertainty in the initialization period $t = 0$. Tildes denote scenario-dependent random parameters or decision variables. Returns are associated with time intervals. $\tilde{R}_{it}$ ($t = 1, \dots, T$) are the (random) gross returns for asset i between $t - 1$ and t . The scenario generation and statistical properties of returns are discussed below.

The budget constraints are

$$\sum_{i=1}^N P_{i0}(1 + tcp_i) = \sum_{i=1}^N S_{i0}(1 - tcs_i) + C_0 \quad t = 0 \quad (5)$$

and

$$\sum_{i=1}^N \tilde{P}_{it}(1 + tcp_i) = \sum_{i=1}^N \tilde{S}_{it}(1 - tcs_i) + C_t, \quad t = 1, \dots, T - 1 \quad (6)$$

where tcp_i and tcs_i denote asset-specific linear transaction costs for purchases and sales, and C_t is the fixed (nonrandom) net cashflow (inflow if positive).

Portfolio weights can be constrained over linear combinations (subsets) of assets or individual assets via

$$\sum_{i \in U} \tilde{W}_{it} - \theta_U \sum_{i=1}^N \tilde{W}_{it} \leq 0 \quad (7)$$

and

$$-\sum_{i \in L} \tilde{W}_{it} + \theta_L \sum_{i=1}^N \tilde{W}_{it} \leq 0, \quad t = 1, \dots, T - 1 \quad (8)$$

where θ_U is the maximum percentage and θ_L is the minimum percentage of the subsets U and L of assets

$i = 1, \dots, N$ included in the restrictions. θ_U 's, θ_L 's, U 's and L 's may be time dependent.

Risk is measured as a weighted discounted convex function of target violation shortfalls of various types in various periods. In a typical application, the deterministic wealth target $\bar{W}_t$ is assumed to grow by 7.5% in each year. The wealth targets are modeled via

$$\sum_{i=1}^N (\tilde{W}_{it} - \tilde{P}_{it} + \tilde{S}_{it}) + \tilde{M}_t^W \geq \tilde{W}_t, \quad t = 1, \dots, T \quad (9)$$

where $\tilde{M}_t^W$ are nonnegative wealth-target shortfall variables. The shortfall is penalized using a piecewise linear convex risk measure. Stochastic benchmark goals can also be set by the user and are similarly penalized for underachievement. The benchmark target $\tilde{B}_t$ is scenario dependent. It is based on stochastic asset returns and fixed asset weights α_i defining the benchmark portfolio

$$\tilde{B}_t = W_0 \sum_{j=1}^t \sum_{i=1}^N \alpha_i \tilde{R}_{ij} \quad (10)$$

The corresponding shortfall constraints are

$$\sum_{i=1}^N (\tilde{W}_{it} - \tilde{P}_{it} + \tilde{S}_{it}) + \tilde{M}_t^B \geq \tilde{B}_t \quad t = 1, \dots, T \quad (11)$$

where $\tilde{M}_t^B$ is the benchmark-target shortfall. These shortfalls are also penalized with a piecewise linear convex risk measure. If total wealth exceeds the target, a fraction $\gamma = 10\%$ of the exceeding amount is allocated to a reserve account and invested in the same way as other available funds. However, the wealth targets at future stages are adjusted. Additional nonnegative decision variables $\tilde{D}_t$ are introduced and the wealth-target constraints become

$$\begin{aligned} & \sum_{i=1}^N (\tilde{W}_{it} - \tilde{P}_{it} + \tilde{S}_{it}) - \tilde{D}_t + \tilde{M}_t^W \\ & = \bar{W}_t + \sum_{j=1}^{t-1} \gamma \tilde{D}_{t-j}, \quad t = 1, \dots, T-1 \end{aligned} \quad (12)$$

where $\tilde{D}_1 = 0$.

Since pension payments are based on wealth levels, increasing these levels increases pension payments. The reserves provide security for the pension plan's increase in pension payments at each future stage.

The pension plan's objective function is to maximize the expected discounted value of terminal wealth in period T net of the expected discounted penalty costs over the horizon from the convex risk measures $c_k(\cdot)$ for the wealth- and benchmark-targets, respectively,

$$\begin{aligned} & \text{Max} E \left[d_T \sum_{i=1}^N \tilde{W}_{iT} - \lambda \sum_{t=1}^T d_t w_t \right. \\ & \quad \left. \times \left(\sum_{k \in \{W, B\}} v_k c_k(\tilde{M}_t^k) \right) \right] \end{aligned} \quad (13)$$

Expectation is over T period scenarios S_T . The discount factors d_t are related to the interest rate r by $d_t = (1+r)^{-t}$. Usually r is taken to be the three- or six-month Treasury-bill rate. v_k 's are weights for the wealth- and benchmark-shortfalls and the w_t 's are weights for the weighted sum of shortfalls at each stage normalized via

$$\sum_{k \in \{W, B\}} v_k = 1 \quad \text{and} \quad \sum_{t=1}^T w_t = T \quad (14)$$

Such concave objective functions with convex risk measures date back to 1986 [22], were used in the Russell–Yasuda model [7] and are justified in an axiomatic sense in [25]. Nontechnical decision makers find the increasing penalty for target violations a good approach and easy to understand. Allocations are based on optimizing the stochastic linear program.

Applications

Geyer and Ziemba [12] consider four asset classes (European stocks, US stocks, European bonds, and US bonds) with five periods (six stages): twice 1 year, twice 2 years, and 4 years (10 years in total). They assumed discrete compounding, so the mean return for asset i in simulations is $\mu_i = \exp(\bar{y}_i) - 1$ where $\bar{y}_i$ is the mean, based on log returns. Using a 100–5–5–2–2 node structure, they generated 10 000

scenarios. Initial wealth is equal to 100 units, and the wealth target is assumed to grow at an annual rate of 7.5%. They used a risk-aversion index of $R_A = 4$, and the discount factor is equal to 5%, which roughly corresponds with a simple static mean–variance model to a standard 60/40 stock/bond pension fund mix [19].

Assumptions about the statistical properties of returns measured in nominal euros are based on a sample of monthly data from January 1970 for stocks and 1986 for bonds to September 2000. Summary statistics for monthly and annual log returns are shown in Table 2. The US and European equity means for the longer period 1970–2000 were much lower and slightly less volatile than those for the period 1986–2000. The monthly stock returns were nonnormal and negatively skewed. Monthly stock returns were fat tailed, whereas monthly bond returns were close to normal (the critical value of the Jarque–Bera test for $\alpha = 0.01$ is 9.2).

For long-term planning models such as InnoALM, with its one-year review period, however, properties of monthly returns are less relevant. Table 2 shows statistics for annual returns. Although average returns and volatilities remained about the same, one year of data is lost when annual returns are computed and the distributional properties changed significantly. There was negative skewness, but no evidence existed for fat tails in annual returns, except for European stocks (1970–2000) and US bonds.

The mean returns from this sample are comparable to the 1900–2000 101-year mean returns estimated by Dimson [9]. Their estimate of the nominal mean equity return was 12.0% for the United States and 13.6% for Germany and the United Kingdom (the simple average of the two countries means). They estimated mean of bond returns of 5.1% for the United States and 5.4% for Germany and the United Kingdom.

Assumptions about means, standard deviations, and correlations for the applications of InnoALM are listed in Table 3 and are based on the sample statistics presented in Table 4. Projecting future rates of returns from past data is difficult. The equity means from the 1970 to 2000 period are used because the 1986–2000 period had an exceptionally high performance of stocks that is not assumed to prevail in the long run.

The correlation matrices in Table 3 for the three different regimes are based on the regression approach of Solnik *et al.* [29]. Moving average estimates of correlations among all assets are functions of standard deviations of US equity returns. The estimated regression equations are then used to predict the correlations in the three regimes shown in Table 3. Results for the estimated regression equations appear in Table 4. Three regimes are considered, and the assumption is that 10% of the time, equity markets are extremely volatile; 20% of the time, markets are characterized by high volatility; and 70% of the time, markets are normal. The 35% quantile of US equity return volatility defines “normal”

periods. “Highly volatile” periods are based on the 80% volatility quantile and “extreme” periods on the 95% quantile. The associated correlations reflect the return relationships that typically prevailed during those market conditions. The correlations show a distinct pattern across the three regimes. Correlations among stocks tend to increase as stock return volatility rises, whereas the correlations between stocks and bonds tend to decrease. European bonds may serve as a hedge for equities during extremely volatile periods because bond and stock returns, which are usually positively correlated, are then negatively correlated.

This is a major reason using scenario-dependent correlation matrices is a major advance over the sensitivity of using one correlation matrix as is usually assumed.

Optimal portfolios were calculated for seven cases—with and without mixing of correlations and with normal, *t*-, and historical distributions. The “mixing” cases NM, TM, and HM use mixing correlations. Case NM assumes normal distributions for all assets. Case HM uses the historical distributions of each asset. Case TM assumes *t*-distributions with five degrees of freedom for stock returns, whereas bond returns are assumed to have normal

Table 5 Optimal initial asset weights at Stage 1 by case

Case	European stocks	US stocks	European bonds	US bonds
Single-period, mean–variance optimal weights (average periods)	34.8%	9.6%	55.6%	0.0%
NA: No-mixing (average periods) normal distributions	27.2	10.5	62.3	0.0
HA: No-mixing (average periods) historical distributions	40.0	4.1	55.9	0.0
TA: No-mixing (average periods) t -distributions for stocks	44.2	1.1	54.7	0.0
NM: Mixing correlations normal distributions	47.0	27.6	25.4	0.0
HM: Mixing correlations historical distributions	37.9	25.2	36.8	0.0
TM: Mixing correlations t -distributions for stocks	53.4	11.1	35.5	0.0
TMC: Mixing correlations historical distributions; constraints on asset weights	35.1	4.9	60.0	0.0

distributions. The “average” cases NA, HA, and TA use the same distribution assumptions, with no mixing of correlation matrices. Instead, the correlations and standard deviations used in these cases correspond to an “average” period in which 10, 20, and 70% weights are used to compute the averages of correlations and standard deviations in the three different regimes. Comparisons of the average (A) cases and mixing (M) cases are mainly intended to investigate the effect of mixing correlations. TMC maintains all assumptions of case TM but uses Austria’s constraints on asset weights (see Table 5). Eurobonds must be at least 40% and equity at most 40%, and these constraints are binding. Tables 5 and 6 exhibit a distinct pattern: the mixing-correlation cases initially assign a much lower weight to European bonds than the average-period cases. Single-period, mean–variance optimization, and average-period cases (NA, HA, and TA) suggest an approximate 45%/55% stock/bond mix. The mixing-correlation cases (NM, HM, and TM) imply a 65%/35% stock/bond mix. Investing in US bonds is not optimal at Stage 1 in any of the cases, an apparent result of the relatively high volatility of US bonds.

Table 6 shows that the distinction between A and M cases becomes less pronounced over time. European equities, however, still have a consistently higher weight in the mixing cases than in the no-mixing cases. This higher weight is mainly at the expense of Eurobonds. In general, the proportion of equities at the final stage is much higher than in the first stage. This result may be explained by the fact that the expected portfolio wealth at later stages is far above the target wealth level (206.1 at Stage 6), and the higher risk associated with stocks

is less important. The constraints in case TMC lead to lower expected portfolio wealth throughout the horizon and to a higher shortfall probability than in any other case. Calculations show that the initial wealth would have to be 35% higher to compensate for the loss in terminal expected wealth stemming from those constraints. In all cases, the optimal weight of equities is much higher than the historical 4.1% in Austria.

The expected terminal wealth levels and the shortfall probabilities at the final stage shown in Table 6 make the difference between mixing and no-mixing cases even clearer. The mixing-correlation cases yield higher levels of terminal wealth and lower shortfall probabilities.

If the level of portfolio wealth exceeds the target, the surplus, $\bar{D}_j$, is allocated to a reserve account. The reserves in t are computed from $\sum_{j=1}^t \bar{D}_j$ and are shown in Table 6 for the final stage. These values are in monetary units given an initial wealth level of 100. They can be compared with the wealth target 206.1 at Stage 6. Expected reserves exceed the target level at the final stage by up to 16%. Depending on the scenario, the reserves can be as high as 1800. Their standard deviation (across scenarios) ranges from 5 at the first stage to 200 at the final stage. The constraints in case TMC lead to a much lower level of reserves compared with the other cases, which implies, in fact, less security against future increases in pension payments.

Optimal allocations, expected wealth, and shortfall probabilities are mainly affected by considering mixing correlations, but the type of distribution chosen has a smaller impact. This distinction is primarily the result of the higher proportion allocated to equities,

Table 6 Final stage results

Case	European stocks	US stocks	European bonds	US bonds	Expected terminal wealth	Expected reserves at Stage 6	Probability of target shortfall
NA	34.3%	49.6%	11.7%	4.4%	328.9	202.8	11.2%
HA	33.5	48.1	13.6	4.8	328.9	205.2	13.7
TA	35.5	50.2	11.4	2.9	327.9	202.2	10.9
NM	38.0	49.7	8.3	4.0	349.8	240.1	9.3
HM	39.3	46.9	10.1	3.7	349.1	235.2	10.0
TM	38.1	51.5	7.4	2.9	342.8	226.6	8.3
TMC	20.4	20.8	46.3	12.4	253.1	86.9	16.1

if different market conditions are taken into account by mixing correlations.

The results of any asset-allocation strategy crucially depend on the expected returns. Geyer and Ziemba investigated the effect by parameterizing the forecasted expected equity returns. Assume that an econometric model forecasts that the future return for US equities is between 5 and 15%. The mean of European equities is adjusted accordingly so that the ratio of equity means and the mean bond returns shown in Table 6 is maintained. Geyer and Ziemba retain all other assumptions of case NM (normal distribution and mixing correlations). As expected, the results are sensitive to the choice of the mean return; see [8] and [18, 19]. If the mean return for US stocks is assumed to equal the long-run mean of 12%, as estimated in [9], the model yields an optimal weight for equities of 100%. A mean return for US stocks of 9%, however, implies an optimal weight of less than 30% for equities.

Positive effects on the pension fund performance induced by the stochastic, multiperiod planning approach will be realized only if the portfolio is dynamically rebalanced, as implied by the optimal scenario tree [12]. Figure 5 compares the cumulated monthly returns obtained from the rebalancing strategy for the two cases with a buy-and-hold strategy that assumes that the portfolio weights on January 1992 were fixed at the optimal TM weights throughout the test period. In comparison to the buy-and-hold strategy or the performance using TA results, for which rebalancing does not account for different correlation and volatility regimes, rebalancing on the basis of the optimal TM scenario tree provided a substantial gain.

The model, developed in 2000, proved to be very useful. In 2006, Konrad Kontriner (Member of the

Board) and Wolfgang Herold (Senior Risk Strategist) of Innovest stated:

The InnoALM model... has become the only consistently implemented and fully integrated proprietary tool for assessing pension allocation issues within Siemens AG worldwide. [...] The key elements that make InnoALM superior to other consulting models are the flexibility to adopt individual constraints and target functions in combination with the broad and deep array of results, which allows to investigate individual, path dependent behavior of assets and liabilities as well as scenario based and Monte-Carlo like risk assessment of both sides. [...] The implementation of a scenario based asset allocation model will lead to more flexible allocation restraints that will allow for more risk tolerance and will ultimately result in better long term investment performance.

Conclusions

Some key points concerning the stochastic programming approach to asset-liability management are as follows:

- *Point 1*: Means are by far the most important part of the distribution of returns, especially the direction. One must estimate future means well or one can quickly travel in the wrong direction, which usually leads to losses or underperformance, or complete disaster if one is overlevered.
- *Point 2*: Mean–variance models are useful as a basic guideline when one is in an assets-only situation. Professionals adjust means using mean-reversion, James–Stein, or truncated estimators and constrain output weights. Asset positions should not be changed unless the advantage of the change is significant. Mean–variance analysis should not be used with liabilities and other

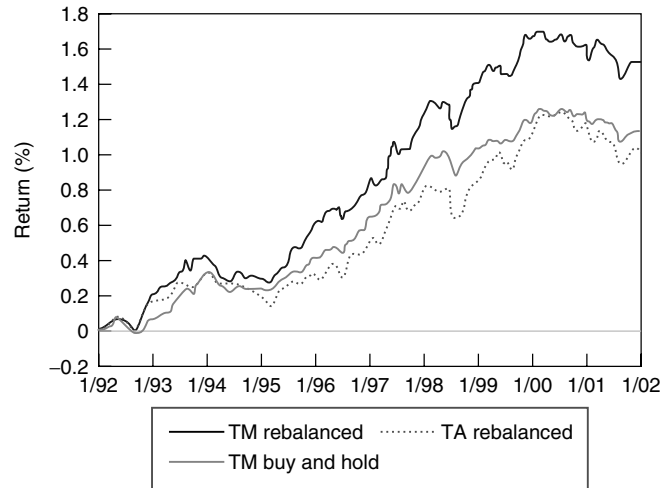

Figure 5 Cumulative monthly returns for different strategies, 1992–2002 [Reproduced from Geyer and Ziemba, 2008. © INFORMS.]

major market imperfections, except as a first test analysis.

- *Point 3:* Trouble arises when one overbets and a bad scenario occurs. Thus, overbetting should not be done when there is any possibility of a bad scenario occurring, unless the bet is protected by some type of hedge or stop loss.
- *Point 4:* Trouble is exacerbated when the expected diversification does not hold in the scenario that occurs. Thus, one must use scenario-dependent correlation matrices because simulations around historical correlation matrices are inadequate for extreme scenarios.
- *Point 5:* When a large decline in the stock market occurs, the positive correlation between stocks and bonds fails and they become negatively correlated. Thus, when the mean of the stock market is negative, bonds are more attractive, as is cash.
- *Point 6:* Stochastic programming scenario-based models are useful when one wants to look at aggregate overall decisions, with liabilities, liquidity, taxes, policy, legal, and other constraints, and have targets and goals one wants to achieve. It, thus, pays to make a complex stochastic programming model when a lot is at stake and the essential problem has many complications.
- *Point 7:* Other approaches, such as continuous-time finance, decision-rule-based stochastic programming, control theory, and so on, are useful

for problem insights and theoretical results. However in actual use, they may lead to disaster unless modified. Black and Scholes [2] option pricing theory infers that one can hedge perfectly with lognormal assets, which can lead to overbetting. Fat tails and jumps arise frequently and can occur without warning. Thus, one should be careful of the assumptions, including implicit ones, of theoretical models. The results should be used with caution no matter how complex and elegant the math or how smart or famous the author. Remember, one has to be very smart to lose millions and even smarter to lose billions.

- *Point 8:* One should not be concerned with getting all the scenarios exactly right when using stochastic programming models. Instead, one should worry about having the problem periods laid out reasonably and make sure the scenarios basically cover the means, the tails, and the chance of what could happen. If the current situation has never occurred before, use one that is similar to add scenarios. For a crisis in Brazil, use Russian crisis data, for example. The results of stochastic programming will give one good advice when times are normal and keep one out of severe trouble when times are bad. Those using stochastic programming models may lose 5, 10, or 15%, but they will not lose 50, 70, or 95%, as some investors and hedge funds have. Thus, if the

scenarios are more or less accurate and the problem elements are reasonably modeled, stochastic programming will give good advice. One may slightly outperform in normal markets, but one will greatly outperform in bad markets when other approaches may blow up.

- *Point 9:* Advances in computing power and modeling expertise have made stochastic programming modeling much less expensive to implement. Such models, which are still complex and require approximately six months to develop and test, cost a couple of hundred thousand dollars. A small team can make a model for a complex organization quite quickly at fairly low cost compared with what is at stake.
- *Point 10:* Eventually, as more disasters occur and more successful stochastic programming models are built and used, they will become popular. Thus, the ultimate goal is to have them in regulations, such as VaR. Although VaR does more good than harm, its safety is questionable in many applications. Conditional VaR is an improvement, but for most people and organizations, the nonattainment of goals is more than proportional (i.e., convex) in the nonattainment.

Passport Options

A passport option is a call option on a traded account, giving the buyer the right to choose his/her strategy (within some limits) and to keep all the gains generated from this strategy while letting the seller cover any losses. In contrast to other exotic options, the value of the traded account (also termed the *wealth of the buyer*) is treated as a security underlying an option. Since the buyer of this option retains profits but cannot make losses, it can be thought of as an option achieving the best total payoff for the buyer. For this reason, the passport option is sometimes called the *perfect trader option* since if a trader buys such an option, he/she cannot lose money beyond the option premium.

The passport option was first sold in foreign exchange markets in the mid-1990s and was later extended to other assets including bonds and interest rate futures. The first study on passport options was done by Hyer *et al.* [10] in 1997 and was heralded by the funds management industry to be a breakthrough in providing derivative-based tools for principal protection of actively managed funds. The resulting contract acts like a stop-loss, limiting the buyer's downside to the premium paid.

Definition and Model

The buyer of a passport option pays a premium and is allowed to switch between short and long positions in an asset over its life. The risky asset in which positions may be taken is denoted by P . The absolute value of the number of units of asset P held at time t , q_t , must be less than or equal to some constant L . We can scale L out of the problem, and hence the restriction becomes $|q| \leq 1$. Gains or losses from this resulting trading strategy are accumulated, and when the option expires at T , the buyer is given any profits from the strategy, but does not pay for any losses.

If we denote the wealth at time t , generated by the trading strategy q_t , by X_t , the passport option payoff at T is

$$\max[0; X_T] = X_T^+ \quad (1)$$

The payoff of the passport option is contingent on the strategy q_t undertaken by the buyer, and thus we cannot define a unique price simply by taking

the discounted risk-neutral expectation of the payoff in the usual way (*see*, for instance, **Risk-neutral Pricing**). We need to assume that the buyer attempts to maximize profits, and thus the seller charges the maximum price over all allowable strategies. This leads to the formulation for the option price:

$$V(t, P_t, X_t) = \sup_{|q_t| \leq 1} e^{-r(T-t)} \mathbb{E}_t X_T^+ \quad (2)$$

where $\mathbb{E}_t$ denotes risk-neutral expectation conditional on information at time t . Note that if the optimal strategy is not followed by the buyer, then the seller has charged more than necessary to hedge and will in fact superhedge or super-replicate.

To define a useful model, we must elaborate on how the wealth or the value of the traded account is generated. The value of this account X_t corresponding to strategy q_t follows

$$dX_t = q_t dP_t + \mu(X_t - q_t P_t) dt \quad (3)$$

with initial value X_0 . The interpretation is that the buyer invests in q units of the risky asset P and the remainder earns interest rate μ (which could be different from the riskless rate of r). The dynamics of the risky asset P will be taken to be an exponential Brownian motion for the time being (we generalize this later):

$$dP_t = \nu P_t dt + \sigma P_t dW_t \quad (4)$$

where ν is the drift (r if a nondividend paying stock, $r - \delta$ if a dividend paying stock, or $r - f$ if foreign currency), σ is the volatility of the asset, and W is a standard Brownian motion.

The Hamilton–Jacobi–Bellman (HJB) equation (*see Expected Utility Maximization*) for the stochastic control (*see Stochastic Control*) problem (2) can be written as

$$\sup_{|q_t| \leq 1} \left[-rV + \dot{V} + V_P P \nu + (\mu X + q P (\nu - \mu)) V_X + \frac{1}{2} \sigma^2 P^2 (V_{PP} + q^2 V_{XX} + 2q V_{PX}) \right] = 0 \quad (5)$$

with boundary condition $V(T, p, x) = x^+$. The above equality holds for $q_t = q_t^*$, where q_t^* attains the supremum in equation (2). This is a nonlinear parabolic partial differential equation (PDE) in two space variables.

The analysis can be simplified if we make the additional assumption that $\mu = \nu = r$, which is the so-called symmetric case. This is assuming that money in the bank earns the riskless rate and the asset grows at rate r . Under this assumption, an explicit price for the passport option and an expression for the optimal strategy q_t^* can be found. In this case, the value of the traded account when discounted by the riskless rate becomes a martingale under the risk-neutral pricing measure. This is the key point that is used in the mathematics to simplify the pricing.

Note that under the symmetric case, the stock may not pay dividends or be a foreign currency. These cases fit into the nonsymmetric framework and must be priced *via* numerical solution of the PDE. Such problems were studied by Andersen *et al.* [2] and Ahn *et al.* [1]. For this article, we continue to be in the symmetric framework to enable us to illustrate the main points of passport pricing.

Pricing

There are two main techniques used in the study of passport option pricing: the partial differential equation (see **Partial Differential Equations**) approach and the probabilistic approach. When the model setup falls into the symmetric case, a closed-form solution is obtainable for the passport option under exponential Brownian motion *via* both of these techniques. There are two issues in solving the pricing problem: to identify the optimal strategy and to calculate the value *via* the expression in equation (2).

Optimal Strategy

We first give some justification for the optimal strategy. Under the symmetric framework, the optimal strategy is found to be given as

$$q_t^* = -\text{sgn}(X_t) \quad (6)$$

where

$$\text{sgn}(y) = \begin{cases} 1, & y > 0 \\ -1, & y \leq 0 \end{cases} \quad (7)$$

This implies the buyer should be long up to the maximum allowed when behind ($X_t \leq 0$) and short up to the maximum when ahead ($X_t > 0$). A solution of this form is called *bang-bang* as it

switches between the two extremes. This solution can be shown to be optimal in a variety of ways. Hyer *et al.* [10], Andersen *et al.* [2], and Ahn *et al.* [1] reduce the dimension of the HJB equation by writing $V(t, P, X) = P\phi(t, z)$ with $z = X/P$ and then from this it was deduced that the strategy is optimal. In contrast, Shreve and Vecer [12] (see also Vecer and Shreve [13]) make the same transformation and then apply a stochastic comparison theorem to achieve the result. Interestingly, the form of the optimal strategy in equation (6) remains unchanged if we generalize the asset price dynamics to allow for diffusion models (under the assumption that the diffusion coefficient is nondecreasing in S). This is shown in [7] using stochastic coupling techniques.

The Option Price

We also follow Henderson and Hobson [7] (and Henderson [5] as well as Delbaen and Yor [3]) in deriving a representation for the price of the passport option using probabilistic methods. The reader is referred to these sources for more technical details and assumptions. As mentioned above, probabilistic techniques allow us to use more general asset prices, namely, P may follow a diffusion. The discounted value of the traded account and the discounted asset price are denoted by $G_t = e^{-rt} X_t$ and $S_t = e^{-rt} P_t$, respectively. Then if

$$dS_t = S_t \sigma(S_t, t) dW_t \quad (8)$$

we have $dG_t = q_t dS_t$, and (under appropriate assumptions) G_t is a martingale under the risk-neutral measure. Using Tanaka's formula and the Skorokhod lemma, the passport option price in equation (2) can be represented as

$$\begin{aligned} \sup_{|q_t| \leq 1} e^{-r(T-t)} \mathbb{E}_t X_T^+ &= \sup_{|q_t| \leq 1} e^{rt} \mathbb{E}_t G_T^+ \\ &= \sup_{|q_t| \leq 1} e^{rt} \left[G_t^+ + \frac{1}{2} \mathbb{E}_t L_{t,T}^G(0) \right] \\ &= \sup_{|q_t| \leq 1} e^{rt} \left[\frac{1}{2} \mathbb{E}_t (M_T^* - |G_t|)^+ \right. \\ &\quad \left. + G_t^+ \right] \end{aligned} \quad (9)$$

where $L_{t,T}^G(0)$ is the local time of G over time t to T (see **Local Times**) and $M_z^* =$

$\sup_{u \leq z} \int_t^u -q \operatorname{sgn}(G) dS$. Using the knowledge of the optimal strategy, the price is reduced to

$$\frac{1}{2} \mathbb{E}_t \left(e^{rt} \sup_{t \leq r \leq T} S_r - P_t - |X_t| \right)^+ + X_t^+ \quad (10)$$

The representation (10) holds for diffusion models with the assumption that the diffusion coefficient $S\sigma(S, t)$ is nondecreasing in S . Under the exponential Brownian motion model where $\sigma(S, t) = \sigma$, a constant, the passport price can be calculated explicitly to be

$$\begin{aligned} X_t^+ + \frac{1}{2} \Big[& P_t(N(d) - N(d - \sigma\sqrt{T-t})) \\ & + \sigma\sqrt{T-t}(N'(d) - dN(d)) \\ & - |X_t|N(d - \sigma\sqrt{T-t}) \Big] \end{aligned} \quad (11)$$

where N is the cumulative normal distribution function and $d = \frac{-\ln(1+|X_t|/P_t) + \frac{1}{2}\sigma^2(T-t)}{\sigma\sqrt{T-t}}$. The price in equation (11) was obtained by Andersen *et al.* [2] by solving a rescaled one-dimensional PDE, by Shreve and Vecer [12] using probabilistic techniques involving a change in measure and a direct derivation of the optimal strategy *via* Hajek's theorem [4], and by Henderson [5] and Henderson and Hobson [7] using the probabilistic arguments summarized here.

Related Options and Further Work

The representation of the passport option price in equation (10) shows that the price is closely related to the price of a lookback option (*see Lookback Options*). From this knowledge, we can deduce that the passport option has a high premium, since lookback options are expensive. This should be anticipated from the fact that a passport option gives the buyer downside protection and upside potential. As with lookback options, the high price of a passport option is its main drawback. The variants discussed below may be cheaper, but each of these limits the buyers trading differently.

Variants on the passport option have been developed and these options on a traded account allow the buyer to switch between positions α_t and β_t where $\alpha_t \leq \beta_t$ in the asset S . A passport option corresponds to the choice $\alpha_t = -1$ and $\beta_t = 1$. Other variants introduced in [12] are the vacation call [$\alpha_t = 0, \beta_t =$

1] and vacation put [$\alpha_t = -1, \beta_t = 0$]. They show that many options are a special case of options on a traded account, including European and American calls and puts and Asian options. Lipton [11] also discussed some similarities between the passport option and Asian options. (*See* articles **American Options** and **Call Options** for descriptions of European and American options and **Asian Options** for descriptions of Asian options.)

Passport options on futures and forwards contracts can be used to develop new hedging tools for commodity exposures. Typical hedging involves the sale or the purchase of futures or forwards, or vanilla options on the commodity. (*See*, for instance, **Commodity Risk; Commodity Forward Curve Modeling**.) These are European in nature and cannot be used to capture daily or weekly movements in future curves. A hedging strategy that allows for speculation on the upside, while retaining a downside hedge, involves a passport option on additional trading as well as a standard forward or futures hedge. This may appeal to the hedger, as they will not be any worse off than if they had hedged passively, but have upside also. Compared to buying a put option, this new strategy is expensive. However, after adjusting for cost, the new strategy has a higher probability of being in the money and thus is a better hedge against the worst outcomes. These ideas were developed in the work of Henderson *et al.* [9]. Further results on passport options are derived in [6] where coupling techniques and the mean comparison theorem of Hayek [4] are used to give option price comparison results. Henderson and Hobson [8] study pricing of passport options under stochastic volatility models. Delbaen and Yor [3] extend the probabilistic pricing argument to obtain a new theorem about martingales, study the case with nonzero interest rate *via* hitting times for Bessel processes, and solve the symmetric case when trading is permitted at discrete times. For results concerning discrete trading, see also [1].

VICKY HENDERSON

Ruin Theory

The earliest ruin problem was formulated by de Moivre around 1730. A gambler has an initial fortune of u monetary units (an integer). Each time he plays (heads or tails in coin tossing, black or red at the roulette, *etc.*), his fortune goes one up or down according to whether he wins or loses. If the fortune becomes 0, the gambler is ruined. He decides *a priori* to stop gambling if his fortune reaches $v \geq u$. If the probability of a win is p , what is then $\psi_v(u)$, the probability of getting ruined as opposed to reach the target v ?

The classical ruin problem of insurance mathematics is rather similar: u is the initial reserve of the insurance company, and incoming premiums make the reserve go up, payments to insurance holders make it go down. One then considers $\psi(u)$, the ruin probability defined as the probability that the reserve ever becomes nonpositive (note that this is a one-barrier problem, whereas the gambler's ruin problem involves two barriers).

A general mathematical formulation of this and related types of problems is a stochastic process $\{R(t)\}$ (corresponding to the fortune of the gambler or the insurance company at time t) and the stopping times

$$\begin{aligned}\tau_v(u) &= \inf\{t : R(t) \notin (0, v) | R(0) = u\} \\ &= \inf\{t : R(t) \leq 0 \text{ or } R(t) \geq v | R(0) = u\} \\ \tau(u) &= \inf\{t : R(t) \leq 0 | R(0) = u\}\end{aligned}\quad (1)$$

In broad terms, ruin theory is concerned with deriving properties of these stopping times. In particular, in the two-barrier setting one typically has $\psi_v(u) < \infty$ and could ask for $\mathbb{P}(R(\tau_v(u)) \geq v)$ or $\mathbb{P}(R(\tau_v(u)) \leq 0)$. In the one-barrier setting, the main object of interest is the probability $\psi(u) = \mathbb{P}(\tau(u) < \infty)$ of eventual ruin. Other quantities of interest are the distribution of $\tau(u)$, needed to say something about the finite horizon ruin probability $\psi(u, T) = \mathbb{P}(\tau(u) \leq T)$, and the deficit $-R(\tau(u))$ after ruin (*see Gerber–Shiu Function*).

Ruin problems occur also in finance. A simple example is an equity default swap (*see Equity Swaps*) that pays a certain amount if a security price drops by a certain amount (say 50%) in a time period $[0, T]$. The price of the equity default

swap then involves the risk-neutral probability (*see Risk-neutral Pricing*) that this happens, which can easily be represented in the form $\psi(u, T)$. A few more examples occur in barrier options (*see Barrier Options*). For example, a digital down-and-in option will pay the amount 1 if the security price $Z(t)$ goes below L before T , but is above $K > L$ at time T ($Z(T) > K$). A standard down-and-in option will pay instead $(Z(T) - K)^+$ under the same conditions.

Explicit Solutions

In the rest of the article, we assume that $\{R(t)\}_{t \geq 0}$ has stationary independent increments (though there is a considerable literature on extensions such as Markovian regime, *see Regime-switching Models*, jumps at the epochs of a renewal process, *etc.*). Beyond the simple random walk in the gambler's ruin problem, key examples are Brownian motion (with drift μ and variance constant σ^2 , say) and the Cramér–Lundberg risk model

$$R(t) = u + ct - \sum_{i=1}^{N(t)} V_i \quad (2)$$

where c is the premium rate, N is the Poisson process of times of arrivals of claims, and $V_1, V_2, \dots$ are the claim sizes.

The gambler's ruin problem is easily solvable: conditioning upon the outcome of the first play gives

$$\psi_v(u) = p\psi_v(u+1) + (1-p)\psi_v(u-1) \quad (3)$$

when $0 < u < v$. Subject to the obvious boundary conditions $\psi_v(0) = 1$, $\psi_v(v) = 0$, this set of equations has a unique solution that can be seen to be

$$\psi_v(u) = \frac{[(1-p)/p]^v - [(1-p)/p]^u}{[(1-p)/p]^v - 1} \quad (4)$$

(for $p = 1/2$, this needs to be modified to $\psi_v(u) = 1 - u/v$).

What with other models? The simplest example is Brownian motion with drift μ and variance σ^2 , where conditioning upon $R(h)$ and letting $h \downarrow 0$ gives $\psi_v(u) = \mu\psi'_v(u) + \sigma^2\psi''_v(u)/2$. Together with $\psi_v(0) = 1$, $\psi_v(v) = 0$, this differential equation is easily solved to get

$$\psi_v(u) = \frac{e^{-\gamma u} - e^{-\gamma v}}{1 - e^{-\gamma v}} \quad \text{where } \gamma = 2\mu/\sigma^2 \quad (5)$$

for $\mu > 0$ and $\psi_v(u) = 1 - u/v$ for $\mu = 0$. A more elegant and general approach uses martingales (see **Martingales**). The Wald exponential martingale is

$$W(t) = W_\alpha(t) = \exp \{-\alpha R(t) - t\kappa(\alpha)\} \quad (6)$$

where $\kappa(\alpha) = \log \mathbb{E} \{-\alpha R(1)\}$ (the so-called Lévy exponent, see **Lévy Processes**). A particularly important choice of α is γ , the nonzero solution of $\kappa(\gamma) = 0$ and going under names such as the adjustment coefficient, the Cramér–Lundberg root and so on. Indeed, for this case $W(t) = \exp \{-\alpha R(t)\}$, and since $R(\tau_v(u)) = v$ when $R(\tau_v(u)) \geq v$ (and similarly $R(\tau_v(u)) = 0$ when $R(\tau_v(u)) \leq 0$) for Brownian motion, optional stopping gives

$$\begin{aligned} e^{-\gamma u} &= W(0) = \mathbb{E} W(\tau_v(u)) \\ &= \psi_v(u)e^0 + (1 - \psi_v(u))e^{-\gamma v} \end{aligned} \quad (7)$$

In the Brownian case, $\kappa(\alpha) = -\alpha\mu + \alpha^2\sigma^2/2$, and so $\gamma = 2\mu/\sigma^2$. Inserting in equation (7) and solving for $\psi_v(u)$, equation (5) follows easily. For the following, note that

$$\kappa(\alpha) = \lambda(\mathbb{E}e^{-\alpha V_i} - 1) + \alpha c \quad (8)$$

for the Cramér–Lundberg model (here γ is only explicit for a few examples, in particular exponential V_i , cf. equation (11) below).

For further generalizations, basically one needs to be able to say something about the overshoot $R(\tau_v(u)) - v$, given $R(\tau_v(u)) \geq v$ and the undershoot $-R(\tau_v(u))$ given $R(\tau_v(u)) \leq 0$. A basic example is the Cramér–Lundberg model with the V_i exponential, say, at rate μ . Then by the memoryless property of the exponential distribution, $-R(\tau_v(u))$, given $R(\tau_v(u)) \leq 0$ is again exponential(μ) so that

$$\mathbb{E}[\exp \{\gamma R(\tau_v(u))\} | R(\tau_v(u)) \leq 0] = \frac{\mu}{\mu + \gamma} \quad (9)$$

Since $R(\tau_v(u)) = v$ when $R(\tau_v(u)) \geq v$ (the process has no upward jumps), it follows that

$$\begin{aligned} e^{-\gamma u} &= W(0) = \mathbb{E} W(\tau_v(u)) \\ &= \psi_v(u) \frac{\mu}{\mu + \gamma} + (1 - \psi_v(u))e^{-\gamma v} \end{aligned} \quad (10)$$

However, if λ is the Poisson intensity, then

$$\kappa(\alpha) = \lambda \left(\frac{\mu}{\mu + \alpha} - 1 \right) + \alpha c \implies \gamma = \lambda/c - \mu \quad (11)$$

Solving equation (10) for $\psi_v(u)$ yields an explicit expression for $\psi_v(u)$, and letting $v \rightarrow \infty$ we then get one of the classical formulas in ruin theory,

$$\psi(u) = \frac{\lambda}{c\mu} \exp \{-(\lambda/c - \mu)u\} \quad (12)$$

in the exponential case.

A generalization of equation (10) is to let the V_i be phase-type, say with initial vector $\mathbf{v}$, phase generator $\mathbf{T}$ and exit rates $\mathbf{t}$. Then ([1 p. 227])

$$\psi(u) = \mathbf{v}_+ \exp \{(\mathbf{T} + \mathbf{t}\mathbf{v}_+)u\} \quad \text{where } \mathbf{v}_+ = -\lambda\mathbf{v}\mathbf{T}^{-1}/c \quad (13)$$

The derivation involves some additional steps, but again, the crucial feature is that one can control the undershoot: the distribution of $-R(\tau_v(u))$, given $R(\tau_v(u)) \leq 0$ is determined by the phase in which 0 is downcrossed. Thus we have a finite set of unknowns, which motivates the matrix form of equation (13).

Bounds and Symptotics

Formula (13) is more or less the end of the road with regard to explicit solutions, even for the simple Cramér–Lundberg model. Therefore, inequalities and approximations play a major role in the area.

The celebrated *Lundberg's inequality* states that

$$\psi(u) \leq e^{-\gamma u} \quad (14)$$

A simple proof of equation (14) (and many other inequalities and approximations) is to use change of measure: for each θ with $\kappa(\theta) < \infty$, consider the risk process with λ changed to $\lambda_\theta = \lambda \mathbb{E}e^{-\theta V_i}$ and the distribution of V_i given by $\mathbb{E}_\theta e^{\alpha V_i} = \mathbb{E}e^{(\alpha-\theta)V_i} / \mathbb{E}e^{-\theta V_i}$. Then

$$\begin{aligned} \psi(u) &= \mathbb{P}(\tau(u) < \infty) \\ &= \mathbb{E}_\theta \exp \{\theta[R(\tau(u)) - u] - \theta\kappa(\theta)\tau(u)\} \end{aligned} \quad (15)$$

Taking $\theta = \gamma$ and bounding $R(\tau(u))$ below by 0 immediately yields equation (14). A more elaborate argument involving the $\mathbb{P}_\theta$ -limit distribution of $R(\tau(u))$ gives the other main result in the area,

going under the name of the Cramér–Lundberg approximation,

$$\psi(u) \sim Ce^{-\gamma u}, u \rightarrow \infty, \text{ where } C = \frac{1 - \kappa'(0)/c}{\kappa'(\gamma)/c - 1} \quad (16)$$

The results (14) and (17), both require a light-tailed assumption, namely, the existence of γ (and for equation (17) in addition that $\kappa'(\gamma) < \infty$). With heavy tails, the situation is completely different. Assume that V is subexponential (see **Heavy Tails in Insurance; Heavy Tails**; for example, the tail is regularly varying, $\mathbb{P}(V > v) = L(v)/v^\alpha$ with $\alpha > 1$ and $L(\cdot)$ slowly varying). Then

$$\psi(u) \sim \frac{\lambda/\mathbb{E}V}{(c - \lambda/\mathbb{E}V)\mathbb{E}V} \int_u^\infty \mathbb{P}(V > y) dy, u \rightarrow \infty \quad (17)$$

a result that is often associated with the names (in alphabetical order) of Borovkov, Cohen, Embrechts, Pakes, Veraverbeke, and von Bahr.

Finite Horizon Ruin Probabilities

The density or the distribution function of $\tau(u)$ is essentially only explicit for Brownian motion: if $\sigma^2 = 1$, then

$$\begin{aligned} \mathbb{P}_\mu(\tau(u) \in dt) \\ = \frac{u}{\sqrt{2\pi}t^{3/2}} \exp\left\{-\mu u - \frac{1}{2}\left(\frac{u^2}{t} + \mu^2 t\right)\right\} \end{aligned} \quad (18)$$

However, if one is satisfied with transforms, the situation is somewhat better, at least for the Cramér–Lundberg model: with exponential claims, one has

$$\mathbb{E}[e^{-a\tau(u)}; \tau(u) < \infty] = e^{-\theta u}(1 - \theta/\mu) \quad (19)$$

where θ is the largest root of $\kappa(\theta) = ac$ or, equivalently, of the quadratic $\theta^2 + (\lambda/c - \mu + ac)\theta - ac\mu$. For general claim size distributions, one has to go to double transforms to get a reasonably simple for-

mula:

$$\begin{aligned} \int_0^\infty e^{bu} \mathbb{E}[e^{-a\tau(u)}; \tau(u) < \infty] du \\ = \frac{-ac/r(a) - \kappa(b)/b}{\kappa(b) + ac} \end{aligned} \quad (20)$$

where $r(a)$ is the smallest solution of $-ac = \kappa(r(a))$.

The asymptotics of the ruin time $\tau(u)$ is, however, well understood. In the light-tailed setting, $\tau(u)/u$ has limit (conditional upon $\tau(u) < \infty$) $1/\kappa'(\gamma)$ as $u \rightarrow \infty$, and there is further a central limit theorem for $(\tau(u) - u/\kappa'(\gamma))/u^{1/2}$. In the subexponential case, there is again a limit for $\tau(u)/c(u)$ for some suitable constants $c(u) \rightarrow \infty$, but the limit is random (e.g., Pareto in the regularly varying case where $c(u) = u$), not constant as for light tails. These statements translate easily into approximations for

$$\begin{aligned} \psi(u, t) = \mathbb{P}(\tau(u) \leq t) \\ = \psi(u) \mathbb{P}(\tau(u) \leq t | \tau(u) < \infty) \end{aligned} \quad (21)$$

Further approximations worth mentioning are the corrected diffusion approximation and the saddle-point approximation. For these, as well as the remaining topics discussed in this article, see Asmussen [1]. Some additional standard monographs in the area are Bühlmann [2], Gerber [3], and Grandell [4].

Cramér–Lundberg Estimates

Cramér–Lundberg estimates and bounds are used to estimate ruin probabilities of the surplus in an insurance risk model. The studies of insurance risk models can be dated back to 1909, when F. Lundberg presented his paper “On the theory of risk” at the Sixth International Congress of Actuaries (see [14]). In the paper, a shifted compound Poisson process was used to model the surplus of an insurance company. The model was further investigated by H. Cramér (see [2]). Because of the pioneering work of Lundberg and Cramér on the shifted compound Poisson model, the shifted compound Poisson model is often referred to as the Cramér–Lundberg risk model/process or the classical compound Poisson risk model these days. For a comprehensive coverage of insurance risk models, see **Ruin Theory** and **Insurance Risk Models**.

In the Cramér–Lundberg risk model, the number of claims from an insurance portfolio of an insurance company follows a Poisson process $N(t)$ (see **Poisson Process**) with intensity λ , the successive claim amounts X_n , $n = 1, 2, \dots$, are positive, independent, and identically distributed random variables with common distribution function $P(x)$, $x > 0$, and they are assumed to be independent of the number of claims process $N(t)$. The aggregate claims from the insurance portfolio up to time t are thus given by $S(t) = \sum_{n=1}^{N(t)} X_n$; this is a compound Poisson process with mean $E\{S(t)\} = \lambda t E(X)$ and variance $Var\{S(t)\} = \lambda t E(X^2)$, where X is a generic copy of X_n 's (see **Accumulated Claims**). Suppose that the company has initial surplus $u \geq 0$ and receives premiums continuously at annual rate c . The company's surplus process is written as $U(t) = u + ct - S(t)$. In order to ensure that the premium incomes cover the insurance claims over time, it is generally assumed that $c > \lambda E(X)$. Let $\theta = [c - E\{S(1)\}]/E\{S(1)\}$. Then c may be written as $c = (1 + \theta)\lambda E(X)$. Thus, θ is the risk premium for the expected claim of one monetary unit per unit time and is called the *relative security loading*.

Several quantities associated with the surplus process are of central interest. Among them are the first time that the surplus becomes negative or the company is insolvent $T = \inf\{t; U(t) < 0\}$ and

the probability that the ruin event occurs $\psi(u) = Pr\{T < \infty\}$. Thanks to the independent increments property of the Poisson process, it can be shown that the probability of ruin $\psi(u)$ satisfies the defective renewal equation

$$\psi(u) = \frac{1}{1 + \theta} \int_0^u \psi(u - x) dP_e(x) + \frac{1}{1 + \theta} [1 - P_e(u)] \quad (1)$$

where $P_e(x)$ is the equilibrium distribution of $P(x)$ and is given by

$$P_e(x) = \frac{\int_0^x [1 - P(y)] dy}{E(X)} \quad (2)$$

As the probability of ruin is the solution of the defective renewal equation (1), methods in renewal theory apply. The negative solution $-\kappa$, when it exists, of the following equation

$$\int_0^\infty e^{-zx} dP_e(x) = 1 + \theta \quad (3)$$

or its equivalent form

$$cz + \lambda \tilde{p}(z) - \lambda = 0 \quad (4)$$

where $\tilde{p}(z)$ is the Laplace–Stieltjes transform of $P(x)$, plays a key role in the analysis of time-of-ruin related quantities of the risk model. Equation (3) or (4) is referred to as the Cramér–Lundberg equation or condition, and κ the Lundberg adjustment coefficient. It is straightforward to show that the function $e^{\kappa u} \psi(u)$ satisfies a proper renewal equation and thus the key renewal theorem applies. As a result, one has the Cramér–Lundberg estimate or approximation of ruin probabilities

$$\psi(u) \sim \frac{\theta E(X)}{E\{Xe^{\kappa X}\} - (1 + \theta)E(X)} e^{-\kappa u}, \text{ as } u \rightarrow \infty \quad (5)$$

Moreover, a simple exponential upper bound, called the *Lundberg Bound* or *Lundberg inequality*, is obtainable:

$$\psi(u) \leq e^{-\kappa u}, \quad u \geq 0 \quad (6)$$

The results (5) and (6) are two of the most celebrated results in ruin theory (see **Ruin Theory**).

Expected Discounted Penalty Function

Two other important quantities related to the time of ruin are the surplus immediately before ruin $U(T-)$ and the deficit at ruin $|U(T)|$, where $T-$ is the left limit of T . In the seminal paper [7], Gerber and Shiu introduced the expected discounted penalty function (see **Gerber–Shiu Function**) to provide a unified treatment of the time of ruin T , the surplus $U(T-)$ and the deficit $|U(T)|$. The function is defined as

$$\begin{aligned} \Psi(u) \\ = E \left[e^{-\delta T} w(U(T-), |U(T)|) \mid I(T < \infty) \mid U(0) = u \right] \end{aligned} \quad (7)$$

where $w(x, y)$ is the penalty for a surplus amount of x immediately before ruin and a deficit amount of y at ruin, and δ is interpreted as either a force of interest or a Laplace transform variable. The probability of ruin $\psi(u)$, the joint distribution of $U(T-)$ and $|U(T)|$, and more, are the special cases of the expected discounted penalty function. There have been many papers analyzing the expected discounted penalty function for various insurance risk models. It has been shown that the expected discounted penalty function $\Psi(u)$ satisfies a defective renewal equation. As a result, a Cramér–Lundberg estimate for the expected discounted penalty function $\Psi(u)$ is obtainable.

Distributional Generalizations

It is easy to verify that the solution of the defective renewal equation (1) is the (right) tail of a compound geometric distribution. Hence, the results for the probability of ruin may also apply to compound geometric distributions. If $G(x)$ is the distribution function of a compound geometric distribution with geometric parameter ϕ and the secondary distribution $F_Y(x)$, one has the Cramér–Lundberg estimate

$$1 - G(x) \sim C e^{-\kappa x}, \quad x \rightarrow \infty \quad (8)$$

with

$$C = \frac{1 - \phi}{\kappa \phi E \{ Y e^{\kappa Y} \}} \quad (9)$$

and the Lundberg inequality

$$1 - G(x) \leq e^{-\kappa x}, \quad x \geq 0 \quad (10)$$

where κ is the Lundberg adjustment coefficient when the equilibrium $P_e(x)$ is replaced by $F_Y(x)$. Further generalizations include the refinements and generalizations of the exponential bound to new worse than used (NWU) bounds and distributional generalizations of the Cramér–Lundberg estimate and the Lundberg inequality to other compound distributions. See [4, 10] and [17], and references therein.

Further Extensions

The Cramér–Lundberg risk model has been extended in several ways. Dufresne and Gerber [3] added a Brownian motion to the Cramér–Lundberg risk model:

$$U(t) = u + ct - S(t) + \sigma W(t) \quad (11)$$

where $\{W(t)\}$ is the standard Brownian motion. The additional diffusion term may be interpreted as the future uncertainty of the aggregate claims, the future uncertainty of the premium incomes, or the fluctuation of the investment of the surplus. In this situation, the expected discounted penalty function $\Phi(u)$ satisfies the defective renewal equations. Thus, a Cramér–Lundberg estimate similar to equation (4) exists for $\Phi(u)$ and the result can be found in [15].

The model (11) is a special case of Lévy processes (see **Lévy Processes**). A number of papers discuss the probability of ruin for this class of surplus processes. See [9, 11] and [18]. More recently, the expected discounted penalty function for general Lévy processes has been investigated in [5]. Generally, the results for Lévy surplus processes are very similar to those for the model (11).

Another extension is to replace the Poisson process by a renewal process. The resulting risk model is often called the *Sparre Andersen model* as it was first investigated by Sparre Andersen [1]. In this case, the expected discounted penalty function defined by equation (7) still satisfies a defective renewal equation. The defective renewal equation structure implies that Lundberg estimates and bounds hold in this more general situation. For further discussion of these issues, see **Ruin Theory** [8, 12, 16], and references therein.

Financial Applications

The expected discounted penalty function can be used to price American perpetual options. Assume that the price of a risky asset follows a jump-diffusion process under a risk-neutral probability measure: $A(t) = A(0)\exp\{ct + \sigma W(t) - S(t)\}$, $t \geq 0$ where the components in this model are the same as those in equation (11) except that the choice of c is such that the present value process of $A(t)$ is a martingale (see **Itô's Formula**). Consider an American perpetual put option with time- t payoff $\max\{K - A(t), 0\}$, where K is the strike price. The optimal exercise boundary is constant owing to the stationary and independent increment property of the process. Let φ be the constant and the time of exercise thus is

$$T = \inf\{t : A(t) < \varphi\} \quad (12)$$

If we define the initial surplus $u = \ln[A(0)/\varphi]$ and the penalty function $w(x, y) = \max\{K - \varphi e^{-y}, 0\}$, the exercise time T in equation (12) is the time of ruin for the model (11) and the price of the American perpetual put option is the same as the expected discounted penalty function for the model (11). See [6] for details. Further applications include the pricing of perpetual catastrophe equity put options. A catastrophe equity put option is an option contract that allows an insurer to issue a fixed number of convertible preferred shares at a predetermined price to the option writer, when the accumulated catastrophic loss amount of the insurer or a loss index exceeds a prespecified level. For details, see [13].

Actuarial Premium Principles

An actuarial premium principle is a method for assigning an appropriate price for an insurance policy. This price is the amount that has to be paid by the insured for exchanging “risk” with “certainty.” The agreed premium represents an equilibrium between the parties involved. In fact, individual agents look at the price they are willing to pay for hedging (partially or totally) their risks, whereas insurers take into account how much premium they should charge in order to avoid technical ruin and to guarantee the rentability of the underlying insurance portfolio. Premium principles deal with the analysis and the characterization of such equilibrium.

In the first section, we introduce basic notions, an axiomatic characterization, and a review of premium principles. Next, an economic method to interpret the relation between premium principles and market systems is described. Then, we present a unified approach based on a generalized Markov inequality for tail probabilities and show how several types of premium principles can be derived from it.

In the last section, we consider the analysis of insurance portfolios (i.e., collections of insurance contracts) traded in financial markets. In this case, portfolios are transferred either from an insurer to another insurer or from an insurer to the market (*see Securitization*). We devote the last paragraph to the analysis of pricing such portfolios.

In this article, we focus on the main aspects of the theory of premium principles. Topics that are not covered include insurer profitability and solvency requirements (*see Solvency*).

Notice that in the recent literature, premium principles are often considered as akin to risk measures (*see Convex Risk Measures; Value-at-Risk; Expected Shortfall; Spectral Measures of Risk*).

The Axiomatic Characterization of Premium Principles

Classes of premium principles may be derived from sets of axioms. The introduction of such axioms is not an arbitrary or dogmatic approach but rather an essential step for defining the properties a premium

principle has to satisfy. Indeed, in case a set of axioms proposed does not suit a certain intuition of insurance risk, we could modify it properly. In this way, it is possible to justify an axiomatic characterization by showing its strengths or to criticize it by demonstrating its lack of practical importance.

The analysis of premium principles using an axiomatic characterization was introduced in the actuarial context in [20].

Let us consider a probability space (Ω, F) , where Ω is the set of the scenarios equipped with a σ -algebra F . A risk is a random variable defined on (Ω, F) , that is, $X : \Omega \rightarrow \Re$ is a risk if $X^{-1}((-\infty, x]) \in F$ for all $x \in \Re$. When X takes only positive values, that is, $X \geq 0$, we call it a *risk*. The class of all random variables on (Ω, F) is denoted by $\mathbf{W}$. We equip the measurable space with a probability measure P , which we call the *base probability measure*.

A premium principle π is a functional that assigns a real number to any random variable X in $\mathbf{W}$.

The above definition may be extended to the case where risks are noninsurable, that is, when $\pi[X] = +\infty$.

In the following, we introduce some axioms and properties a premium principles may (or may not) satisfy. All random variables are assumed to be elements of the set $\mathbf{W}$ introduced above.

Monotonicity: π is monotonic if $\pi[Y] \leq \pi[X]$ when $Y(\omega) \leq X(\omega)$ for all $\omega \in \Omega$. π is P -monotonic if $\pi[Y] \leq \pi[X]$ when $Y \leq X$, P -almost sure.

Positive homogeneity (scale invariance, scale equivariance): π is positively homogeneous if $\pi[aX] = a\pi[X]$ for all $a \geq 0$.

Translation invariance (translation equivariance, translativity, consistency): π is translation invariant if $\pi[X + c] = \pi[X] + c$ for all real c .

Subadditivity: π is subadditive if $\pi[X + Y] \leq \pi[X] + \pi[Y]$. If the inequality is reversed, then the property is called *superadditivity*.

Additivity for independent risks: π is additive if $\pi[X + Y] = \pi[X] + \pi[Y]$ for independent $X, Y \in \mathbf{W}$.

Comonotonic additivity: π is comonotonic additive (*see Copulas in Insurance*) if $\pi[X + Y] = \pi[X] + \pi[Y]$ whenever X and Y are comonotonic.

See [17, 23] for a review of independent and comonotonic additive premium principles and [10, 11] for an introduction to comonotonicity.

For taking in account violations of the axioms of subadditivity and positive homogeneity due to liquidity risk (see **Liquidity Premium**), it is possible to replace these two with the requirement by convexity. The interested reader is referred to [1, 16, 22] and **Convex Risk Measures** and also to [12].

Convexity: π is convex if $\pi[aX + (1 - a)Y] \leq a\pi[X] + (1 - a)\pi[Y]$ for all $a \in (0, 1)$.

Law-invariance: π is law invariant if $\pi[X] = \pi[Y]$ in case $X \stackrel{d}{=} Y$.

Preserving stop-loss order: π preserves stop-loss order if $\pi[X] \leq \pi[Y]$ when $E[(X - d)_+] \leq E[(Y - d)_+]$ for all $d \in \mathbb{R}$.

Preserving first-order stochastic dominance (FOSD): π preserves first-order stochastic dominance if $\pi[X] \leq \pi[Y]$ when $P[X \leq x] \geq P[Y \leq x]$ for all $x \in \mathbb{R}$.

These two properties are closely linked to each other. Indeed, the latter is a direct consequence of the former. For a review on the applications of stop-loss and stochastic ordering in actuarial science, see [9].

Positive risk loading: π induces a risk loading if $\pi[X] \geq E[X]$.

Having a positive risk loading is a suitable property because without it an insurer will make a loss in the long run. We will see the relevance of this property comparing the net and the expected value principle.

No rip-off (maximal loss): $\pi[X] \leq \text{ess sup}[X]$.

Not unjustified: π is not unjustified if $\pi[X] = c$, when $X \in \mathbf{W}$ is equal to $c \geq 0$ almost everywhere.

Premium Principles: A Review

In this section, we introduce several premium principles as well as their relevant properties. We also give the definition of the Dutch premium calculation principle.

Note that all the following premium principles implicitly assume the existence of a given utility function (see **Utility Theory: Historical Perspectives; Utility Function**). For an analysis of expected utility theory and subjective expected utility theory, the interested reader is referred to [29, 35]. For more applications of the theory of choice under uncertainty and the utility framework within actuarial science, we refer to [7].

Expected value principle: The expected value principle is given as

$$\pi[X] = (1 + \alpha)E[X] \quad (1)$$

where $\alpha \in \mathbb{R}$. In case $\alpha = 0$ we find the net premium that does not load for risk. This principle is justified by the strong law of large numbers (SLLN). Given that the risk $X = \sum_{i=1}^n X_i$ is linked to a large homogeneous portfolio, let us suppose that X_i are independent and identically distributed (i.i.d.) and their first moment exists and is finite, $E[X_i] = \mu < \infty$, for $i = 1, 2, \dots$. Thus, from the SLLN, we find that

$$\lim_{n \rightarrow \infty} P[|n^{-1}X - \mu| < \varepsilon] = 1 \quad (2)$$

for all $\varepsilon > 0$.

The net premium principle is appropriate only in case insurers are risk-neutral. Indeed from the ruin theory (see **Ruin Theory**), it is known that ruin will inevitably occur whenever there is no loading.

Equivalent utility principle: The equivalent utility premium is obtained for the premium that makes the expected utility of the income $\pi[X] - X$ of the insurer equal to the utility of not accepting the risk. We could assume that the utility function is subjective and the probability measure objective, if we choose the framework introduced in [35]. Otherwise, following the results in [29], the probability measure is also considered to be subjective and not known.

The minimal premium, $\pi^-[X]$, and the maximal premium, $\pi^+[X]$, are derived by solving

$$E[u(w + \pi[X] - X)] = u(w) \quad (3)$$

and

$$E[\bar{u}(\bar{w} - X)] = \bar{u}(\bar{w} - \pi[X]) \quad (4)$$

respectively, where X is a positive random variable, w a real number, and $\bar{u}$ denotes the utility function of the insured and u the one of the insurer.

Thus, the insurer will sell the insurance contract if and only if $\pi[X] \geq \pi^-[X]$, whereas the insured will buy it when $\pi[X] \leq \pi^+[X]$. Hence, the equilibrium price lies in the interval

$$[\pi^-[X], \pi^+[X]]$$

In case both the insurer and the insured are risk-averse (see **Risk Aversion**), it follows that

$$E[X] \leq \pi^-[X] \leq \pi^+[X] \quad (5)$$

Different specifications of the utility function yield different expressions $\pi^-[X]$ and $\pi^+[X]$. It is not guaranteed that an explicit expression for $\pi^-[X]$ or $\pi^+[X]$ is obtained.

As a final remark, the difference $\pi^+[X] - \pi^-[X]$ denotes the mark-up price. It is maximum in the case of insurer's monopoly, whereas in a competitive insurance market it tends to zero.

Distortion principle: The distortion principle as a premium principle was introduced in [36, 37] and it can be seen as an attempt to overcome some of the shortcomings of the expected utility theory. Indeed as a consequence of the Allais paradox [3], some nonexpected utility theories were proposed. The distortion principle refers to Yaari's dual theory [38]. Yaari showed that the amount of money $\pi(v)$ (certainty equivalent) that makes it indifferent to hold the lottery V or to receive the amount $\pi(v)$ with certainty is given as

$$\pi(v) = -\int_{-\infty}^0 (1 - g(\bar{F}_V(v)))dv + \int_0^{+\infty} g(\bar{F}_V(v))dv \quad (6)$$

where $\bar{F}_V(v) = 1 - P[V \leq v]$. The function $g : [0, 1] \rightarrow [0, 1]$ is known as *distortion function* and it is nondecreasing and it fulfills $g(0) = 0$ and $g(1) = 1$.

Using the distorted distribution function $F_g^*(x) = 1 - g(\bar{F}_V(x))$ together with equation (6), we get that $\pi(v) = \int_{-\infty}^{+\infty} x dF_g^*(x)$.

For an overview on distortion risk measures, the reader is referred to [9, 13].

Proportional hazard (PH) principle: The PH principle arises as a special case of the distortion principle when $\bar{g}(x) = x^{1/\alpha}$, $\alpha \geq 1$, and it is given as

$$\begin{aligned} \pi[X] = & -\int_{-\infty}^0 (1 - (\bar{F}_X(x))^{1/\alpha}) dx \\ & + \int_0^{+\infty} ((\bar{F}_X(x))^{1/\alpha}) dx \end{aligned} \quad (7)$$

See [36] for a review of the properties of this premium principle.

Mean value principle: The mean value principle arises as the root π of the following equation:

$$f(\pi) = E[f(x)] \quad (8)$$

where f is a nondecreasing and nonnegative function defined on $\mathfrak{R}$.

Variance principle: For some $\alpha > 0$, the variance principle is given as

$$f(\pi) = E[X] + \alpha \text{Var}[X] \quad (9)$$

Standard deviation principle: For some $\alpha > 0$, the standard deviation principle is given as

$$f(\pi) = E[X] + \alpha \sqrt{\text{Var}[X]} \quad (10)$$

The last two principles are built on the expected value by including a risk loading that is proportional to the variance or the standard deviation of the risk. Denneberg [8] suggested to replace the standard deviation with the absolute deviation. See [27, 30] for a generalization of the variance and standard deviation principles to the dynamic case.

Exponential principle: The exponential principle is given as

$$\pi[X] = \frac{1}{\alpha} \log E[\exp(\alpha X)] \quad (11)$$

where $\alpha > 0$. The exponential principle represents a special case of the equivalent utility principle in the case of an exponential utility function; see [17, 23, 26].

Esscher principle: The Esscher premium is given as

$$\pi[X] = \frac{E[Xe^{\alpha X}]}{E[e^{\alpha X}]} \quad (12)$$

where $\alpha > 0$. This premium is based on the notion of Esscher transform (*see **Esscher Transform***), introduced by Esscher [15]. Let us consider a random variable X and a positive real number α such that $E[e^{\alpha X}] < \infty$; one considers a transformed distribution function:

$$F_{\tilde{X}}(x) = \int_0^x \frac{e^{\alpha X}}{E[e^{\alpha X}]} dF_X(x) \quad (13)$$

In this way, we obtain the Esscher measure that is mutually absolute continuous, that is, equivalent (*see **Equivalence of Probability Measures***), with respect to the original probability measure. For a review of the characterizations of Esscher principle, we refer to [32]. In the last paragraph, we demonstrate the importance of Esscher transform in an insurance pricing framework.

Swiss principle: The Swiss premium π is the root of the following equation in π :

$$E[w(W - p\pi)] = w((1 - p)\pi) \quad (14)$$

4 Actuarial Premium Principles

Table 1 All premiums mentioned above are law invariant. All principles are not unjustified except the expected value principle for $\alpha > 0$

for a nonnegative and nondecreasing function w defined on $\mathfrak{R}$ and a given parameter $0 < p \leq 1$.

Both the equivalent utility principle and the mean value principle can be obtained as particular cases of the Swiss premium principle; see [20].

Dutch principle: The Dutch principle is given as

$$\pi[X] = E[X] + \theta E[(X - \alpha E[X])_+],$$

$$\alpha \geq 1, \quad 0 < \theta \leq 1 \quad (15)$$

The Dutch premium principle was introduced in [31].

Orlicz principle: The Orlicz principle is given by the root of

$$E[\psi(X/\pi)] = 1 \quad (16)$$

where $X \geq 0$ and ψ is a normalized Young function on $\mathfrak{R}_+ \cup \{0\}$. This premium reflects a change in risk in a proportional change in premium (Table 1).

The Economic Method

In 1980, Bühlmann derived the economic premium principle in contrast to classical premium principles that depend only on the risk to be covered; see [4]. He took into account general market conditions and proposed a premium principle based on economic arguments. In this way, the economic premium principle is a function that associates with a random variable X representing insurance risk and a random variable Z denoting market risk π , that is, $\pi : (X, Z) \rightarrow \mathfrak{R}$.

Let consider a market with n insurer agents. We suppose that the insurer i bears risk X_i , $i = 1, 2, \dots, n$, and that his/her risk aversion is characterized by the exponential utility function $u_i(x) = \frac{1}{\alpha_i}(1 - e^{(-\alpha_i x)})$. Bühlmann obtained the following expression for the equilibrium pricing density for the risk X :

$$\pi[X, Z] = \frac{E[Xe^{\alpha Z}]}{E[e^{\alpha Z}]} \quad (17)$$

that is, the Esscher premium; see [4]. Moreover, it can be considered as a Pareto optimal risk exchange. In the case where X and $Z - X$ are independent to each other, we derive the standard premium principle:

$$\begin{aligned} \pi[X, Z] &= \frac{E[Xe^{\alpha X}]E[Xe^{\alpha(Z-X)}]}{E[e^{\alpha X}]E[e^{\alpha(Z-X)}]} \\ &= \frac{E[Xe^{\alpha Z}]}{E[e^{\alpha Z}]} = \pi[X] \end{aligned} \quad (18)$$

Bühlmann derived the above result using the concept of a pricing density (pricing kernel and state price deflator). The interested reader is referred to [28].

Bühlmann generalized this result in [5], allowing for insurers with general utility functions. For an extension of the above model to the dynamic multi-period case, see [25].

Table 2 Premium principles derived from the generalized Markov inequality

Premium principle	$\nu(x)$	$\phi(x, \pi)$
Mean value	1	$\frac{f(x)}{f(\pi)}$
Equivalent utility	1	$\frac{u(\pi - x)}{u(0)}$
Swiss	1	$\frac{\omega(x - p\pi)}{\omega((1 - p)\pi)}$
Orlicz	1	$\psi(x/\pi)$

A Unified Approach by Markov Inequality for Tail Probabilities and VaR

A unified approach for generating premium principles based on the Markov inequality of tail probabilities has been introduced in [21]. Indeed, using two exogenous functions $\nu(\cdot)$ and $\phi(\cdot, \cdot)$ (Table 2), an exogenous parameter $\alpha \leq 1$, and assuming that $\nu(\cdot)$ is both nonnegative and nondecreasing and fulfills $\phi(x, \pi) \geq 1_{\{x > \pi\}}$, where $1_{\{x > \pi\}} = \begin{cases} 1 & \text{if } x > \pi \\ 0 & \text{if } x < \pi \end{cases}$, then by the generalized Markov inequality we find that

$$P[X > \pi] \leq \frac{E[\phi(X, \pi)\nu(X)]}{E[\nu(X)]} \quad (19)$$

Focusing on the upper bound of the above equation, if it is set to the confidence level $\alpha \leq 1$, we have that

$$P[X > \pi] \leq \frac{E[\phi(X, \pi)\nu(X)]}{E[\nu(X)]} = \alpha \leq 1 \quad (20)$$

When $\alpha = 1$, equation (21) can be used for generating several well-known premium principles:

$$\frac{E[\phi(X, \pi)\nu(X)]}{E[\nu(X)]} = 1 \quad (21)$$

It should be remarked that this unified approach is also directly linked to the quantile-based approach. Indeed, for all ϕ, ν , using the results shown above, we find that $\pi \geq \inf\{x \in \mathfrak{R} : P[X \leq x] \geq 1 - \alpha\}$; see [20].

Insurance Pricing

This section is devoted to the analysis of insurance portfolios (i.e., collections of insurance contracts) traded in financial markets.

Although traditional actuarial pricing of insurance relies on economic theory of decision under uncertainty, financial pricing of contingent claims mainly relies on risk-neutral valuation, which can be justified within a no-arbitrage setting (*see Arbitrage: Historical Perspectives; Arbitrage Pricing Theory*). Even if this assumption may seem unrealistic in the case of traditional insurance markets, it is suitable for insurance products traded on financial markets; see [2, 7, 33, 34]. Moreover, owing to the incompleteness of insurance markets, we will observe an infinite number of equivalent martingale measures (*see Equivalence of Probability Measures; Martingales*) and hence an uncountable set of possible prices.

Insurance prices can be derived by means of the Esscher transform, as suggested by Gerber and Shiue [18, 19]. These authors defined the Esscher transform for exponential Lévy processes (*see Lévy Processes*), that is, processes with independent and stationary increments. Under the Esscher transform probability measure, it is possible to establish a change of measure for a random variable. Choosing suitable Esscher parameters, discounted prices become martingales and thus no-arbitrage prices can be calculated. In the case where equivalent martingale measure is unique, it is derived by the Esscher transform. Otherwise, if it is not unique, as is usual in the case of insurance markets, the equivalent martingale measure can be derived by the Esscher transform assuming the existence of a representative agent that maximizes its expected utility to a power utility function.

The interested reader is referred to [6, 14, 24] for a review of recent developments in this topic.

Reinsurance

In a *reinsurance contract*, one party (the *reinsurer*) agrees to indemnify for a certain premium another party (called the *reinsured*, the *first-line insurer* or also the *ceding company*) for specified parts of its underwritten insurance risk. Hence, reinsurance is a form of *risk sharing* between insurance companies (cf. [3]). One among the main motivations for an insurance company to buy reinsurance is to reduce the probability of suffering losses that it cannot easily cope with, in particular, the appearance of excessively large or unusually many claims from the underwritten policies. Also, reinsurance is a way to increase the underwriting capacity (which is particularly but not exclusively relevant for smaller insurance companies) and can be interpreted as a (virtual) increase in the solvency (see **Solvency**) capital of the ceding company. Replacing a part of the random costs (claims) by fixed costs (premiums) is the core insurance activity and helps the policy holders to stabilize their business. But this also applies to the first-line insurer as a reinsurance customer and reinsurance can increase the effectiveness of the marketplace. For the same reason, a reinsurance company may itself, again for some suitable premium, pass on parts of the reinsured risks to another reinsurer (both domestic and international), which is then called *retrocession*. For the general concept of the *need for reinsurance* see, for example, Gerber [16] and Schnieper [25].

The type and amount of reinsurance coverage may be negotiated for individual risks in the portfolio (*facultative reinsurance*). But predominantly *reinsurance treaties* are signed, which are obligatory agreements that specify the type and amount of reinsurance coverage for an entire portfolio of risks within an insurance branch (usually for a time horizon of one year).

Among the crucial questions in the context of reinsurance are:

- Which type of reinsurance form is appropriate in a given situation?
- How much reinsurance should be purchased?
- What should be the premium?

Forms of Reinsurance

Let $X(t) := \sum_{i=1}^{N(t)} X_i$ denote the aggregate claim amount in an insurance portfolio up to time t , where

the counting process N_t specifies the number of claims up to time t and the random variables X_i denote the individual claim sizes. In every reinsurance treaty, this amount is split into $X(t) = D(t) + R(t)$, where $D(t)$ is the amount that the insurance company retains for itself (the *deductible*) and $R(t)$ is the *reinsured* amount to be covered by the reinsurance company.

There are two types of proportional reinsurance forms.

Quota-Share Reinsurance

A very common and simple reinsurance form is the quota-share (QS) treaty, where one has

$$R(t) := a X(t), \quad D(t) := (1 - a) X(t) \quad (1)$$

for some proportionality factor $0 < a < 1$. In this case, it is straightforward to calculate the distribution of $R(t)$ and $D(t)$, once the distribution of $X(t)$ is known.

Surplus Reinsurance

While in a QS treaty also small claims are reinsured (which the first-line insurer often wants to keep for himself), a surplus treaty only reinsures claims X_i whose corresponding insured sum Q_i exceeds some retention M . In the latter case, the first-line insurer deducts a proportion M/Q_i and shifts the remaining part to the reinsurer. Consequently,

$$R(t) = \sum_{i=1}^{N(t)} \left(1 - \frac{M}{Q_i}\right) X_i 1_{\{Q_i \geq M\}},$$

$$D(t) = \sum_{i=1}^{N(t)} \left(X_i I(Q_i \leq M) + M \frac{X_i}{Q_i} 1_{\{Q_i > M\}}\right) \quad (2)$$

Surplus treaties are quite popular in practice, in particular in fire, marine, and storm insurance.

Other types of reinsurance forms are of nonproportional nature.

Excess-of-Loss Reinsurance

In an excess-of-loss (XL) treaty, for each individual claim the excess over some retention M is paid by

the reinsurer:

$$R(t) := \sum_{i=1}^{N(t)} (X_i - M)^+, \quad D(t) := \sum_{i=1}^{N(t)} \min(X_i, M) \quad (3)$$

XL covers are, for instance, popular in casualty and windstorm insurance. In most situations, there is an upper limit L of the XL cover of each risk as well, resulting in the treaty

$$R(t) := \sum_{i=1}^{N(t)} \min\{(X_i - M)^+, L\} \quad (4)$$

where L is then the size of the so-called *XL reinsurance layer* (the usual notation is then L *xs* M). It is also common to have an upper limit $k \cdot L$ on the total reinsured amount $R(t)$ for some integer k . In the latter case, one is said to have k *reinstatements* and, depending on the contract, the premium for a higher reinstatement often only has to be paid once the lower reinstatement is used up.

A variant of XL reinsurance is the *per-event XL cover* (or sometimes called *catastrophe XL cover*), where all claims due to some external event such as a storm or an earthquake are first added and then treated as a single claim in an XL contract (avoiding the issue that for many small claims the XL treaty may not provide sufficient protection).

Stop-Loss Reinsurance

The stop-loss (SL) treaty acts on the aggregate claim amount $X(t)$ of the portfolio:

$$R(t) := \left\{ \sum_{i=1}^{N(t)} X_i - C \right\}^+, \quad D(t) := \min(X(t), C) \quad (5)$$

where C is some retention. In general, there is again an additional upper limit on $R(t)$.

In practice, often combinations of the above reinsurance forms are employed (together with upper limits on the total reinsurance cover).

Large-Claim Reinsurance

Let $\{X_1^*, X_2^*, \dots, X_{N(t)}^*\}$ denote the order statistics of the claims ordered according to their size. Then the

largest claims reinsurance is defined through

$$R(t) := \sum_{i=1}^r X_{N(t)-i+1}^*, \quad D(t) := \sum_{i=1}^{N(t)-r} X_i^* \quad (6)$$

that is, the reinsurer covers the r largest claims of the portfolio that have occurred up to time t (which again usually is 1 year). Another variant called *excedent du cout moyen relatif* (ECOMOR) was introduced by Thépaut [27] with a reinsured amount of the form

$$R(t) := \sum_{i=1}^{N(t)} \{X_i - X_{N(t)-r}^*\}^+ \quad (7)$$

so that in this case the reinsurer covers only that part of the r largest claims that overshoots the random retention $X_{N(t)-r}^*$. Such a contract gives the reinsurer protection against claim inflation, since if the claim amounts increase, the retention will also increase.

Although theoretically appealing, large-claim reinsurance treaties are rarely applied in practice.

Reinsurance Premiums

In the first place, reinsurance is a specific form of insurance. Consequently, the principles of premium calculation (*see Actuarial Premium Principles*) can, to some extent, also be applied in the reinsurance setting, once the moments or even the distribution of the number and the size of the reinsured claims are available (although costs and loading factors will in general be different). Extreme value statistics is of vital importance in this context, since typically the reinsured claims are heavy tailed and their distribution has to be estimated, often on the basis of only a few data points (*see Heavy Tails in Insurance* and [14]).

Whereas for proportional reinsurance the actuarial reinsurance premium will simply be the corresponding proportion of the premium that the first-line insurer has received for the underlying risks (minus some acquisition and administration costs), the situation for nonproportional reinsurance is more involved.

The claim number process for the reinsured claims in an XL treaty can be interpreted as an independent thinning of the point process (*see Point Processes*) that generates the claims for the first-line insurer. For many practically relevant examples, the resulting

claim number process for the reinsurer is then of the same form with just some parameters modified (see, e.g., [4]). For the premium calculation of an XL treaty with retention M , under the assumption of independence between the number and the sizes of the claims as well as identically distributed claim sizes, often the *reduction effect*

$$r(M) := \frac{E(D(t))}{E(X(t))} = \frac{1}{E(X)} \int_0^M (1 - F(w)) dw \quad (8)$$

is used, which turns out to be the *equilibrium distribution function* of the distribution function F of an individual claim X . In practice, one distinguishes between *exposure rating*, where the reinsurer uses the portfolio and premium information of the first-line insurer, and *experience rating*, which is mainly based on the previous claim experience of the XL layer itself. Especially, the latter method often faces the challenge of having only a few data points available, in which case credibility estimates (see **Credibility Theory**) may be used. Another important aspect in XL treaties is potential claims inflation, which may be substantial (as the time until settlement of a claim may be large) and would often just affect the reinsurer. Hence, typically some *index clause* is arranged, which splits the amount of claims inflation between the first-line insurer and the reinsurer.

For SL treaties, the aggregate claim distribution (see **Accumulated Claims**) of the first-line insurance portfolio will be the crucial quantity to determine suitable reinsurance premiums, using, for instance, generalized stop-loss transforms to determine moments of the reinsured claim amount (for numerical and algorithmic issues, see [20]).

Premium calculations for large-claim reinsurance contracts are more involved, but several asymptotic results using extreme value theory are available (see [4] for a survey). Note that for all these treaties it is also important to adequately assess the possible dependence among the risks, as this may drastically influence the appropriate premium (see, for instance, [12]).

In addition to the resulting actuarial premium, the actual reinsurance premium will also be influenced by other factors like competition, volume of the portfolio, and perhaps a loading that accounts for potential *moral hazard* and *adverse selection*. Here moral hazard refers to the tendency of the reinsured

not to be as strict in the claim settlement process as without reinsurance (see, e.g., [13]), whereas adverse selection accounts for the asymmetry of information of the cedant and the reinsurer on the underlying risk in general (see [19]). Also, for contracts like the XL treaty, the reinsurer typically has no insight into the number and sizes of the claims below the retention and needs to get information from other sources, which also increases the costs (see, e.g., [17, 18]). General considerations on planning in reinsurance can be found in [26].

Robustness questions of reinsurance premiums are discussed in Brazauskas [8]. In addition, the economic environment influences the pricing of reinsurance risks (see [1, 2]).

Choice of Reinsurance

Each reinsurance form has its particular advantages and disadvantages in terms of the type of protection it provides (frequency risk, large-claim risk), premium calculation, practical handling, administration and processing of loss estimation (including issues like moral hazard and adverse selection). An insurer may have a concrete objective such as to maximize expected profit after reinsurance (subject to a certain security level condition) or to minimize the probability of ruin after reinsurance (see **Ruin Theory**). There are a number of theoretical results available which under specific assumptions on the underlying premium principle identify the optimal reinsurance form with respect to given maximization criteria and constraints (see [4] for an overview). A natural and close connection between such optimality questions and utility theory (see **Utility Function**) is, for example, discussed by Borch [7] and Bühlmann and Jewell [9]. For instance, under an expected value premium principle of the reinsurer and a given reinsurance premium, an SL contract maximizes the expected utility of terminal wealth for any risk-averse utility function (a result attributed to K. Arrow, see **Arrow, Kenneth**). As a consequence, in this setting an SL contract also minimizes the retained variance $\text{Var}(D)$ of the first-line insurer. On the other hand, under a variance or standard deviation premium principle and a fixed value of $\text{Var}(R)$, a QS contract minimizes $\text{Var}(D)$ [5, 23]. Already these two examples illustrate that the selected reinsurance premium principle plays a decisive rule for the optimal decision. Also, the

optimality results usually heavily depend on the type and amount of transaction costs involved. In recent years many refinements of such optimality results have been developed (see [4, 21] for a general survey on this topic). For a dual approach in the framework of solvency in finance and insurance, see [29]. In the collective model, it is also quite common to look for reinsurance strategies that minimize the Lundberg adjustment coefficient (see **Cramér–Lundberg Estimates**; [15] and [10]). An overview on optimal dynamic reinsurance strategies to minimize the probability of ruin can be found in [24] (see **Ruin Theory and Stochastic Control in Insurance**). For other optimization criteria, see [30].

In practice, the concrete form and amount of reinsurance choice for a certain portfolio often also will be influenced by experience, availability of reinsurance offers, and current market prices.

Reinsurance and Finance

The financial component in any insurance and reinsurance activity has become more important over the last years, not the least due to higher interest rates, longer time horizons for claim settlement, and the general need to combine the analysis and management of assets and liabilities (see, e.g., [28]). Financial pricing of reinsurance contracts in various contexts is discussed in [11] (see **Insurance Derivatives**), and note that a (re)insurance market is incomplete, (see **Complete Markets**). Since reinsurance is a global business, foreign exchange risk (see **Foreign Exchange Markets**) also has to be considered (cf. [6]).

Nowadays, classical reinsurance is often complemented by other mechanisms to cope with risk (summarized under the name *alternative risk transfer*) that have a certain financial flavor such as *captives*, *finite risk reinsurance*, *multi-trigger products*, and *contingent capital* (cf. [22]). Further bridging the gap between insurance and finance, insurance companies also started to transfer some of their risk directly to the capital market (see **Securitization**). This includes *reinsurance sidecars*, where investors act like a QS reinsurer, as well as the issuance of catastrophe bonds (see **Catastrophe Bonds**). Recently, some structured insurance-linked products such as *catastrophe collateralized debt obligations* (CDOs) (see **Collateralized Debt Obligations (CDO)**) have also been issued in

the financial market, which sometimes receive quite competitive credit ratings for their tranches. At the same time, some of the traded catastrophe CDOs offer loss coverage that can be significantly cheaper than in classical reinsurance contracts.

Catastrophe Bonds

Catastrophe bonds (also called *cat bonds*) were developed to facilitate direct transfer of catastrophe insurance risk (see **Insurance Risk Models**) from (re)insurers (see **Reinsurance**) and corporations (referred to as *sponsors* for the cat bonds) to investors. As a market innovation in the form of insurance risk securitization, cat bonds were designed to protect sponsoring companies from financial losses caused by large natural catastrophes (such as hurricanes and earthquakes), as an alternative or supplement to traditional reinsurance (see **Reinsurance**). From the sponsor's perspective, the fully collateralized nature of cat bonds provides an important alternative source of capital capacity. From the investors' perspective, the past performances of cat bonds have been very attractive and cat bonds provide further diversification relative to the typical financial asset portfolios.

Cat losses covered under the cat bond are often characterized by a loss-exceedance curve, $S(x) = \Pr\{X > x\}$, that is, the probability that the cat loss X will exceed amount $\$x$. Investors of a cat bond are generally provided with a loss-exceedance curve $S(x)$ that is obtained either

- by running company exposure data through commercially available cat modeling software, or
- by designing payout functions along some parametric indicators (e.g., the Richter scale of an earthquake at a specified location, an aggregate industry loss index, etc.).

The following information is embedded in a loss-exceedance curve $S(x)$:

- the expected frequency of default (see **Credit Risk**); and
- the recovery rate, given default.

As compensation for credit risks (see **Credit Risk**), cat bonds normally offer investors yields that are higher than the risk-free interest rate (e.g., the London interbank offered rate (LIBOR); see **Bond**). The excess yields spread over the risk-free rate should more than compensate for the expected default rate, since it should also contain risk load for uncertainties associated with the default risk.

For investors, it is desirable to compare the relative attractiveness of the yields spreads between cat bonds and corporate bonds. In order to compare risk-adjusted performance of various asset classes, what is needed is a common yardstick that is applicable to all types of risks. For mutual funds (see **Mutual Funds**), a popular measure of risk-adjusted performance is the Sharpe ratio (see **Capital Asset Pricing Model**), namely, the excess return per unit of volatility. The Sharpe ratio works well for assets whose returns follow normal distributions. However, for a single cat bond issue, the traditional Sharpe ratio concept is not applicable since the asset return is skewed and with jumps: most of the probability mass is centered at zero loss, although there is a small probability of potentially large negative returns. Other pricing methods have been developed for cat bonds to capture the characteristics of cat bond losses.

Lane Pricing Model

Lane [1] proposed the following model for the cat bond yields:

$$\text{EER} = \gamma(\text{PFL})^\alpha(\text{CEL})^\beta \quad (1)$$

where probability of first loss (PFL) is the expected annual frequency of incurring a loss. Conditional expected loss (CEL) represents the average severity as percentage of principal given that a loss occurs. Expected excess return (EER) represents the adjusted spread over LIBOR, further net of expected loss (that is, $\text{PFL} \times \text{CEL}$). EER represents the risk loading.

Lane showed that his model (1) fits reasonably well to empirical prices for a dozen CAT bond transactions in 1999–2000, for which the best-fit parameters were $\gamma = 55\%$, $\alpha = 49\%$, and $\beta = 57\%$.

Probability Transform Method

Wang [2] establishes a pricing method by directly applying the following Wang transform to convert a loss curve S to a price curve S^* :

$$S^*(y) = t(\Phi^{-1}(S(y)) + \lambda) \quad (2)$$

where t represents Student- t distribution with degree of freedom k . The difference in the areas between S^* and S constitutes the risk load. Based on the same 1999–2000 cat bond transaction data as in [1], the estimated parameters of Wang transform in

equation (2) are $\lambda = 0.454$ and the degree of freedom $k = 5$. Here the student- t factor is essential to capture the low frequency and high-severity characteristic of credit losses associated with cat bonds.

Insurance Derivatives

Derivatives are financial instruments whose value depends on some underlying variables. Insurance derivatives are those derivatives that are related to insurance. Roughly speaking, there are two main types of insurance derivatives in the market. The first type is the so-called catastrophe derivatives (see **Catastrophe Bonds**). They are similar to ordinary financial derivatives like options (see **Options: Basic Definitions**) and futures (see **Forwards and Futures**) except that the underlying variables are not financial instruments but insured natural catastrophe risk. The second type is equity-linked products. These are policies sold by insurance companies in which payoffs to the investors are linked to the performance of other financial instruments like equities and stock index.

PCS Catastrophe Insurance Options

A traditional way that insurance companies can get capital injection (in the form of debt or equity) in the event of a natural catastrophe is through the so-called contingent capital programs. This process permits access to risk capital only if following a loss exceeds a certain threshold. However, insurance risk is not transferred in this arrangement. To enhance the claims-paying ability of insurers and reinsurers following severe natural catastrophes, and to take advantage of the global capital markets, securitization (see **Securitization**) of catastrophe insurance risk has been proposed in recent years so that the risk can be transferred from the insurance industry to the capital market.

Catastrophe insurance derivatives (CAT-derivatives) were first developed by the Chicago Board of Trade in 1992. The first generation of derivatives included futures and options of futures. For a detailed description of these contracts, we refer to [29] and [7]. Reference [37] contains a concise summary of catastrophe derivatives. In 1995, the first generation derivatives were replaced by property claim service (PCS) catastrophe insurance options. Underlying these options are some catastrophe loss indices compiled daily by PCS. These indices reflect estimated and published insured losses due to natural catastrophes for a defined region and a defined time period.

Let $X = (X_t)_{t \geq 0}$ be a stochastic process modeling a PCS loss index. The value of this process at time t can be interpreted as the accumulated insured losses (see **Accumulated Claims**) due to natural catastrophes up to time t . The payoff of a European type CAT-derivative with maturity T depends on the value of the index at time T , that is, $\text{payoff} = \phi(X_T)$ for some function ϕ .

Models of the PCS Loss Index

Since the index value represents the accumulated insured losses due to catastrophic events, and catastrophic events occur unpredictably, it is natural to model the loss index by a continuous time stochastic process with jumps (see **Jump Processes**) at random time points. For example, Cummins and Geman [16] modeled the instantaneous claim process as a geometric Brownian motion with jumps:

$$dS_t = \alpha S_{t-} dt + \sigma S_{t-} dW_t + k \cdot dN_t \quad (1)$$

where k is a positive constant representing the losses due to catastrophes and N is an independent Poisson process (see **Poisson Process; Point Processes**) with constant intensity. This Poisson process counts the number of catastrophic events that occurred in the past. The process S models the instantaneous loss amount, and hence accumulated losses up to time t (that is, the index value up to time t) is given by

$$X_t = \int_0^t S(u) du \quad (2)$$

Assuming the market is arbitrage-free (see **Arbitrage Strategy; Fundamental Theorem of Asset Pricing**), or, equivalently, the existence of an equivalent martingale probability measure (see **Equivalent Martingale Measures**), the valuation problem of futures contracts written on the loss index X is equivalent to that of Asian options (see **Asian Options**) written on S with zero exercising price. Therefore, the valuation problem of CAT-futures is transformed to a standard Asian option pricing problem. In [22], the authors have modeled accumulated losses directly by a jump diffusion:

$$dX_t = S_t dt + k dN_t \quad (3)$$

where the process S is a geometric Brownian motion (see **Black-Scholes Formula**) representing

the randomness in the reporting of the claims, k is a positive constant, and (N_t) is a Poisson process with constant intensity. This model preserves the quasi-completeness of insurance derivative markets obtained by applying the Delbaen and Haezendonck methodology [19] to the class of layers of reinsurance (see **Reinsurance**) replicating the call spreads (see **Call Spread**) [21]. To derive a unique price of insurance derivatives written on the index (X_t) , the authors assumed that the insurance market is both arbitrage free and complete. The justification of completeness is that one can choose an equivalent martingale measure that best fits the prices of various reinsurance layers. By using the techniques of stochastic time changes (see **Time Change**) and Laplace transforms, the authors obtained quasi-analytical solutions for CAT-option prices.

Aase [1] modeled the loss index using a compound Poisson process:

$$X_t = \sum_{k=1}^{N_t} Y_k \quad (4)$$

where N , as before, is a Poisson process counting the number of catastrophic events in the past, and Y_k is the jump size of the index at the random time point of occurrence of the k th catastrophe. It was assumed that $Y_1, Y_2, \dots$ form an independent and identically distributed sequence and are independent of the counting process N . The compound Poisson process is commonly used in actuarial risk theory (see **Insurance Risk Models**) to model aggregate losses. The loss index modeled in this way is time homogeneous with independent increments. These properties were justified empirically by the actuarial studies performed by Levi and Partrat [27]. Aase investigated the valuation problems of CAT-futures and derivatives on futures. In the framework of partial equilibrium theory with uncertainty, the author derived closed form formulas under some specific assumptions on the utility functions (see **Utility Function**). A similar model was used by Chang *et al.* [11] to evaluate CAT-futures and futures call spreads. They applied the randomized operational time approach to transform the compound Poisson process to a more trackable pure diffusion. Embrechts and Meister [20] generalized Aase's compound Poisson model to mixed compound Poisson process with stochastic intensity. Similarly, Dassios and Jang [18] used the Cox process to model the claim arrival process for catastrophic

events. As pointed out in [36], a market comprises a risk-free bond and a loss index alone is very often incomplete because of two reasons: (i) the underlying loss index (X_t) is not traded and hence it is impossible to construct a hedging portfolio (see **Hedging**) based on the bond and the index; and (ii) there is no instrument to hedge the stochastic jump sizes of the loss index.

Equity-linked Insurance Products

Traditionally, annuities are contracts sold by insurance companies to provide a stream of fixed payments over the life of the contract. In recent years, variable annuities in the United States are getting more popular with investors. In contrast to traditional annuity products, the payments of a variable annuity are linked to the performance of a portfolio of securities like stocks, bonds, and mutual funds. Through investing in variable annuities, investors can not only participate in the stock market but also partially hedge the downside risk of the market. Nowadays, variable annuities with guaranteed minimum withdrawal benefits (GMWBs) are quite common. Policyholders are allowed to withdraw funds on an annual or semiannual basis without a penalty as long as the withdrawal rate is less than a prespecified level. With the GMWB, the sum of cash flows received by the policyholder is guaranteed to be at least the original premium paid. Other common riders include guaranteed minimum death benefit (GMDB), guaranteed living benefit (GLB), guaranteed minimum income benefit (GMIB), and guaranteed minimum accumulation benefit (GMAB). For example, with the GMDB rider, a variable annuity will pay to the policyholder's beneficiary the greater of the account value or a guaranteed minimum amount (such as the total purchase payments). Products similar to variable annuities are also sold in other countries, such as unit-linked annuities in the United Kingdom and segregated funds in Canada. A concise description of the various guaranteed benefits in these contracts can be found in [29, 30].

A similar product is the equity-indexed annuity (EIA). EIA was first introduced by Keyport Life in 1995, and is one of the most successful innovations in the financial markets in the last decade. The notional amount of EIAs sold has increased dramatically in recent years. Essentially, EIA is an equity-linked

deferred annuity whose returns are based on the performance of an equity mutual fund or a stock index like S&P 500. Moreover, return on the initial premium is guaranteed. On each anniversary of the contract, the insurance company measures the growth of the underlying index and credits that calculated growth to the investors. If the growth is negative, the companies normally would still guarantee a certain minimum rate of return, say 3%. However, the guaranteed rate is typically much less than the rate of return offered on US Treasury securities with the same maturity. Since return on the initial premium is guaranteed, EIA can be regarded as a fixed interest deposit with an embedded call option (*see Call Options*) on an underlying index. Since options are implicitly embedded in EIA contracts, various option pricing and hedging techniques are applicable. For detailed discussions and descriptions on equity-linked insurance products, we refer to [23, 26, 32, 39, 40], and [25].

In the literature, the main emphases about variable annuities and EIA have been on pricing and hedging of the options embedded in the contracts. For example, Brennan and Schwartz [10], Boyle and Schwartz [9], and Bacinello and Ortu [3] used standard martingale techniques to price and hedge the embedded options in variable annuities under the assumption that the market is complete. Moller [32–34] investigates pricing and hedging of insurance contracts in the presence of mortality risk. Bacinello and Ortu [4, 5], Nielsen and Sandmann [37], Miltersen and Persson [31], Bacinello and Persson [6], and Zaglauer and Bauerb [41] studied the situation when interest rate risk presents, assuming that the financial market is complete. In an incomplete market, there is no unique fair option price. Perfect hedge by self-financing trading strategies does not exist. As an alternative to perfect hedge, Boyle and Hardy [8] and Hardy [24] studied delta hedging (*see Delta Hedging*) for the options embedded in contracts with GMDB. Another possible way is to construct hedging strategy that minimizes certain measure of the intrinsic risk. For instance, Moller [32–34] and Lin and Tan [27] studied the effect of mortality risk on the risk minimization hedging strategies in the presence of interest rate risk. Coleman *et al.* [14] studied hedging strategies for options embedded with ratchet features, under both equity (including jump) risk and interest rate risk. They assumed that the market is

complete under mortality risk, but the financial market is incomplete, due to a suitable equity model for fat tails or to discrete hedging. Coleman *et al.* [15] compared the relative performances of delta hedging and dynamic discrete risk minimization hedging strategies in the presence of both jump risk and volatility risk.

Recent research also studied the embedded withdrawal and surrender options of equity-linked insurance products. For example, Bacinello [2] used discrete-time binomial models (*see Binomial Tree*) to study the fair valuation problem of participating policies embedded with a surrender option. Chu and Kwok [13] analyzed the withdrawal right embedded in dynamically protected funds. Siu [38] studied the withdrawal and surrender options of a participating life insurance policy by modeling the underlying assets as Markov-modulated geometric Brownian motion. Cheung and Yang [12] studied the optimal surrender time for equity-linked products in a discrete-time regime-switching model (*see Regime-switching Models*). They examined the impact of the Markov transition matrix on the optimal surrender strategy. Milevsky and Salisbury [30] developed the pricing model of variable annuities with GMWB under both static and dynamic withdrawal policies. In [17], the authors have studied the optimal withdrawal strategy using techniques in singular stochastic control theory (*see Stochastic Control*).

Heavy Tails in Insurance

Heavy-tailed Distributions

In the class of heavy-tailed distribution functions, *subexponential* distribution functions are a special class, which have just the right level of generality for risk measurement in insurance and finance models. The name arises from one of their properties: the fact that their right tail decreases more slowly than any exponential tail. This implies that large values can occur in a sample with nonnegligible probability, which proposes the subexponential distribution functions as natural candidates for situations where extremely large values occur in a sample compared to the mean size of the data. Such a pattern is often seen not only in insurance data, for instance, in fire, wind–storm, or flood insurance (collectively known as *catastrophe insurance*) but also in data from finance and communications engineering; see, for example [1, 6, 7]. Subexponential insurance claims can account for large fluctuations in the risk process of a company. Textbook accounts can be found in [2, 4, 6–8].

We present two defining properties of subexponential distribution functions. Let $(X_k)_{k \in \mathbb{N}}$ be independently and identically distributed positive random variables with distribution function F such that $F(x) < 1$ for all $x > 0$. Denote by $\overline{F}(x) = 1 - F(x)$ for $x \geq 0$, the tail of F , and for $n \in \mathbb{N}$,

$$\begin{aligned} \overline{F^{n*}}(x) &= 1 - F^{n*}(x) \\ &= \mathbb{P}(X_1 + \cdots + X_n > x), \quad x \geq 0 \end{aligned} \quad (1)$$

the tail of the n -fold convolution of F . We then say that F (or X) is subexponential (written $F \in \mathcal{S}$) if one of the following equivalent conditions holds:

- (a) $\lim_{x \rightarrow \infty} \frac{\overline{F^{n*}}(x)}{\overline{F}(x)} = n$ for some (all) $n \geq 2$ and
- (b) $\lim_{x \rightarrow \infty} \frac{\mathbb{P}(X_1 + \cdots + X_n > x)}{\mathbb{P}(\max(X_1, \dots, X_n) > x)} = 1$ for some (all) $n \geq 2$.

The heavy-tailedness of $F \in \mathcal{S}$ is demonstrated by the implications

$$F \in \mathcal{S} \implies \lim_{x \rightarrow \infty} \frac{\overline{F}(x-y)}{\overline{F}(x)} = 1 \quad \forall y \in \mathbb{R} \quad (2)$$

$$\implies \frac{\overline{F}(x)}{e^{-\varepsilon x}} \xrightarrow{x \rightarrow \infty} \infty \quad \forall \varepsilon > 0 \quad (3)$$

A famous subclass of $\mathcal{S}$ is the class of distribution functions with regularly varying tails; see [3]. For a positive measurable function f , we write $f \in \mathcal{R}(\alpha)$ for $\alpha \in \mathbb{R}$ (f is *regularly varying with index* α) if

$$\lim_{x \rightarrow \infty} \frac{f(tx)}{f(x)} = t^\alpha \quad \forall t > 0 \quad (4)$$

Let $\overline{F} \in \mathcal{R}(-\alpha)$ for $\alpha \geq 0$; then it has the representation

$$\overline{F}(x) = x^{-\alpha} \ell(x), \quad x > 0 \quad (5)$$

for some $\ell \in \mathcal{R}(0)$.

For regularly varying distribution tails, we can check (a) for $n = 2$ by splitting the convolution integral and use partial integration to obtain

$$\begin{aligned} \frac{\overline{F^{2*}}(x)}{\overline{F}(x)} &= 2 \int_0^{x/2} \frac{\overline{F}(x-y)}{\overline{F}(x)} dF(y) \\ &\quad + \frac{(\overline{F}(x/2))^2}{\overline{F}(x)}, \quad x > 0 \end{aligned} \quad (6)$$

Immediately, by equation (4), the last term tends to 0. The integrand satisfies $\overline{F}(x-y)/\overline{F}(x) \leq \overline{F}(x/2)/\overline{F}(x)$ for $0 \leq y \leq x/2$; hence, Lebesgue-dominated convergence applies and, since F satisfies equation (2), the integral on the right-hand side tends to 1 as $x \rightarrow \infty$. Examples of distribution functions with regularly varying tail include the Pareto, Burr, transformed beta (also called *generalized F*), log-gamma, and stable distribution functions (see Table 1.2.6 in [4]).

In addition, the lognormal, the two Benktander families, and the heavy-tailed Weibull (shape parameter less than 1) belong to $\mathcal{S}$; see again Table 1.2.6 in [4]. However, a direct proof of this is more difficult than that for the regularly varying case. Subexponentiality is typically established via an integral test for the hazard rate known as *Pitman's criterion* [2].

Application to Insurance

The two main examples in insurance risk theory that use the tail properties of subexponential distributions

are aggregated claims tails and ruin probabilities. The *aggregated claims* denoted by A (see **Accumulated Claims**) are defined as the sum of all claims to the insurance company in a given period. The usual model is

$$A = X_1 + \cdots + X_N \quad (7)$$

where N is the number of claims and $X_1, X_2, \dots$ are the *claim sizes* in the given time interval (N and $(X_k)_{k \in \mathbb{N}}$ are assumed to be independent and $(X_k)_{k \in \mathbb{N}}$ is an independently and identically distributed sequence). The tail of A and the associated quantiles are important for assessing the probability of big losses and for Value-at-Risk (see **Value-at-Risk**) calculations. The main result in the heavy-tailed case states that if the X_k are subexponential, then $(a(u) \sim b(u))$ as $u \rightarrow \infty$ means that $\lim_{u \rightarrow \infty} a(u)/b(u) = 1$

$$\mathbb{P}(A > x) \sim \mathbb{E}(N)\mathbb{P}(X_1 > x) \quad \text{as } x \rightarrow \infty \quad (8)$$

provided in addition $\mathbb{E}(z^N) < \infty$ for some $z > 1$ (cf. [2], Chapter IX, Lemma 2.2).

The classical insurance risk model is the *Cramér–Lundberg model* (cf. [2, 4, 6, 8] and see **Ruin Theory**), where the *claim times* occur at the jump times of a Poisson(λ) process $(N(t))_{t \geq 0}$ (see **Poisson Process**) and the claims $(X_k)_{k \in \mathbb{N}}$ are again an independently and identically distributed sequence with finite mean. The *risk process* is for *initial reserve* $u \geq 0$ and *premium rate* $c > 0$ defined as

$$R(t) = u + ct - \sum_{k=1}^{N(t)} X_k, \quad t \geq 0 \quad (9)$$

Then the *ruin probability* $\psi(u)$ in *infinite time* is the probability that R ever falls below 0, that is, $\psi(u) = \mathbb{P}(\inf_{t \geq 0} R(t) < 0)$. Define the *integrated tail distribution function* F_I by

$$F_I(x) = \frac{1}{\mathbb{E}(X_1)} \int_0^x \bar{F}(y) dy, \quad x \geq 0 \quad (10)$$

If F_I is subexponential (which is satisfied for all subexponential distributions F mentioned above under the condition that they have a finite mean) and $\rho = \lambda \mathbb{E}(X_1)/c < 1$, then

$$\psi(u) \sim \frac{\rho}{1 - \rho} \int_u^\infty \bar{F}_I(y) dy \quad \text{as } u \rightarrow \infty \quad (11)$$

a result that is often associated with the names of (in alphabetical order) Borovkov, Cohen, Embrechts, Pakes, Veraverbeke, and von Bahr.

That F_I plays a role may be understood from the fact that F_I is the distribution function of the first undershoot of $R(t) - u$ below 0 under the condition that $R(t)$ falls below u in finite time. The number M of times, where $R(t)$ achieves a new local minimum in finite time plus 1, is geometrically distributed with parameter $(1 - \rho)$, that is, $\mathbb{P}(M = n) = (1 - \rho)\rho^n, n \in \mathbb{N}_0$. This easily leads to the *Beekman–Bowers–Pollaczek–Khinchine formula*

$$\psi(u) = (1 - \rho) \sum_{n=1}^{\infty} \rho^n \bar{F}_I^{n*}(u), \quad u \geq 0 \quad (12)$$

from which equation (11) is an easy consequence.

For further aspects of ruin theory with heavy tails and a comprehensive set of recent references, see [5].

Insurance Risk Models

The Classical Risk Model

We start by formulating the simplest risk model, which is based on the following independent objects:

1. a Poisson process (see **Poisson Process**) $N = \{N(t); t \geq 0\}$ with $N(0) = 0$ and intensity λ_0 , that is, $E[N(t)] = \lambda_0 t$;
2. a sequence $\{Z_k\}_1^\infty$ of independent and identically distributed (i.i.d.) random variables, having the common distribution function F , with $F(0) = 0$, mean value μ , and variance σ^2 .

The *risk process*, X , is defined by

$$X(t) = ct - \sum_{k=1}^{N(t)} Z_k, \quad \left(\sum_{k=1}^0 Z_k \stackrel{\text{def}}{=} 0 \right) \quad (1)$$

where c is a real constant.

This is the *classical model of the risk business* of an insurance company, where $N(t)$ is to be interpreted as the number of claims on the company during the interval $(0, t]$. At each point of N , the company has to pay out a stochastic amount of money, and the company receives (deterministically) c units of money per unit time. The constant c is called the *gross risk premium* rate.

Many studies based on this model treat *ruin theory* (see **Ruin Theory**). Basic results about ruin probabilities for the classical risk model go back to 1926 [17] and 1930 [6], while the general ideas underlying the risk model go even farther back to 1903 [16]. A stringent treatment, based on Wiener–Hopf methods, is due to Cramér [7].

In risk theory, the most interesting situation is when $c > 0$ and $F(0) = 0$. This case is generally called *positive risk sums*, and includes most nonlife branches and also the ordinary types of life insurance, where a certain amount of money is paid on the death of a policyholder.

There are, however, situations where the circumstances are reversed, that is, where $c < 0$ and $F(0) = 1$ (see **Life Insurance**). The typical example is life annuity—or pension—insurance, where a life annuity rate $-c$ is paid from the company to the policyholder and where the claim, that is, the death of the policyholder, will place an amount of money

corresponding to the “expected pension to be paid” at the company’s free disposal. Thus the claim means an income, or a negative cost, for the company. This situation is generally called *negative risk sums*.

Models for the Occurrence of Claims

A natural extension, at least from a mathematical point of view, of the Poisson process is to consider the case where the occurrence of the claims is described by a renewal process N . Let S_k denote the epoch of the k th claim. A point process is called a *renewal process* (with interoccurrence time distribution K^0) if the variables $S_1, S_2 - S_1, S_3 - S_2, \dots$ are independent and if $S_2 - S_1, S_3 - S_2, \dots$ have the same distribution K^0 . Further, N is called an *ordinary* renewal process if S_1 also has distribution K^0 . N is called a *stationary* renewal process if K^0 has finite mean $1/\lambda_0$ and if S_1 has distribution K given by

$$K(t) = \lambda_0 \int_0^t (1 - K^0(s)) \, ds \quad (2)$$

A Poisson process (see **Poisson Process**) is a renewal process with exponentially distributed interoccurrence times. In that case, the ordinary and stationary versions coincide. Probably, the Poisson process is the most realistic renewal process for describing the occurrence of the claims. This, however, does not mean that it is uninteresting to consider renewal models, since often better mathematical clarity is achieved by explicit use of an interoccurrence time distribution. In connection with ruin theory, the renewal model was first studied in [2] and the corresponding risk process is often called the *Sparre Andersen model*. A detailed treatment is given in [21].

Let us now go back to the Poisson case. It is natural to assume that λ_0 is proportional to the size of the insurance company. Naturally, the size of the company may vary in time. A simple way to take size variation into account is to let N be a nonhomogeneous Poisson process.

Definition 1 A point process N is called a nonhomogeneous Poisson process with intensity function $\lambda_0(t)$ if

- (i) $N(t)$ has independent increments;
- (ii) $N(t) - N(s)$ is Poisson distributed with mean $\int_s^t \lambda_0(\tau) \, d\tau$.

If $\lambda_0(t) \equiv \lambda_0$, we are back to the Poisson process. The *intensity measure* is defined by

$$\Lambda_0(t) \stackrel{\text{def}}{=} \int_0^t \lambda_0(s) \, ds, \quad t \geq 0 \quad (3)$$

It is natural to let $\Lambda_0(t)$ have the representation (3), but it is enough to assume that $\Lambda_0(t)$ is a nondecreasing function with $\Lambda_0(0) = 0$ and $\Lambda_0(t) < \infty$ for each $t < \infty$. If $\Lambda_0(t)$ is continuous, then N is *simple*, that is, $N(t)$ increases exactly one unit at its epochs of increase.

There may also be variation in the underlying risk. Typical examples are automobile insurance and fire insurance. It is natural to describe the underlying risk as a random process $\lambda = \{\lambda(t); t \geq 0\}$ and to let N be the corresponding *Cox process*.

We think of a Cox process N as generated in the following way. First, a realization λ_0 of a random process λ is generated. Conditioned upon that realization, N is a nonhomogeneous Poisson process with intensity function λ_0 . A Cox process is stationary if and only if the underlying random process is stationary.

Let equation (3) the *random intensity measure* be defined by

$$\Lambda(t) \stackrel{\text{def}}{=} \int_0^t \lambda(s) \, ds, \quad t \geq 0 \quad (4)$$

Assume that $E[\Lambda(t)^2] < \infty$ for all $t \geq 0$. Then

$$\begin{aligned} E[N(t)] &= E[\Lambda(t)] \quad \text{and} \quad \text{Var}[N(t)] \\ &= E[\Lambda(t)] + \text{Var}[\Lambda(t)] \quad \text{for all } t \geq 0 \end{aligned} \quad (5)$$

Thus a Cox process is overdispersed relative to a Poisson process.

For details of Cox processes, we refer to [12] or [13].

Example 1 The Mixed Poisson Process A Cox process with underlying random process $\lambda(t) \equiv \lambda$, where λ is a random variable, is called a *mixed Poisson process*. A mixed Poisson process where λ is Γ -distributed is called a *Pólya process* and for any fixed value of t the random variable $N(t)$ is negatively binomially distributed.

The mixed Poisson process is a natural model for the accident pattern of an individual policyholder. For instance, in automobile insurance, λ may describe the skillfulness of the individual as a driver.

The distribution of λ may be regarded as a prior distribution. When the company knows more about the driver, the posterior distribution may be used instead.

In 1940, Ove Lundberg had already presented his thesis [18] about Markov point processes and, more particularly, mixed Poisson processes. The mixed Poisson processes have ever since played a prominent role in actuarial mathematics. A survey of mixed Poisson processes is found in [15].

Example 2 The Ammeter Process Let $\Delta > 0$ be a fixed value and $\{L_k; k = 0, 1, \dots\}$ a sequence of nonnegative, i.i.d. random variables. A rather simple Cox process is obtained by letting

$$\lambda(t) = L_k \quad \text{for } k\Delta \leq t < (k+1)\Delta \quad (6)$$

The Cox process with this intensity is called an *Ammeter process*, since it is essentially the model considered by Ammeter [1]. A modern treatment of the Ammeter process is found in [14] and [15].

Example 3 The Markov-modulated Poisson Process Let $J = \{J(t); t \geq 0\}$ be an M -state Markov process with state space $\{1, 2, \dots, M\}$ and $\{\lambda_1, \lambda_2, \dots, \lambda_M\}$ a set of nonnegative numbers. The Cox process $N(t)$ with $\lambda(t) = \lambda_{J(t)}$ is called a *Markov-modulated Poisson process*.

An equivalent way to express N is to consider M independent Poisson processes $\{N_1, N_2, \dots, N_M\}$ with intensities $\{\lambda_1, \lambda_2, \dots, \lambda_M\}$ and to let the occurrence of the claims follow N_k when $J = k$. More formally, we let $dN(t) = dN_{J(t)}(t)$. This model was first studied in insurance by Reinhard [19], in the case $M = 2$ and exponentially distributed claims, and by Asmussen [3] in the general case.

Example 4 Independent Jump Intensity Intuitively, an independent jump intensity is a jump process where the jump times form a renewal process and where the value of the intensity between two successive jumps may depend only on the distance between these two jumps. More formally, let $\Sigma_k, k = 1, 2, \dots$ denote the epoch of the k th jump of the intensity process and let $\Sigma_0 \stackrel{\text{def}}{=} 0$. Put

$$\begin{aligned} \sigma_n &= \Sigma_n - \Sigma_{n-1} \\ L_n &= \lambda(\Sigma_{n-1}) \end{aligned} \quad n = 1, 2, 3, \dots \quad (7)$$

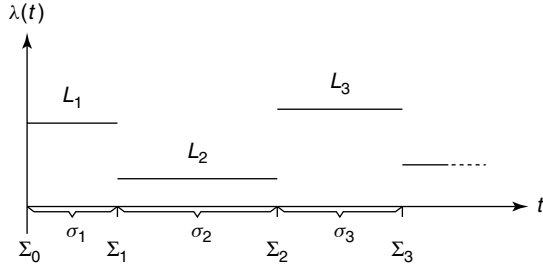

Figure 1 Illustration of notation

Here we understand that λ has right-continuous realizations so that $\lambda(t) = L_n$ for $\Sigma_{n-1} \leq t < \Sigma_n$. These notations are illustrated in Figure 1.

An intensity process λ is called an *independent jump intensity* if the random vectors

$$(L_1, \sigma_1), (L_2, \sigma_2), (L_3, \sigma_3), \dots$$

are independent and if $(L_2, \sigma_2), (L_3, \sigma_3), \dots$ have the same distribution.

This model was introduced in [4].

Models for Cost of Claims and Income

In the classical risk model, the random variables $\{Z_k\}_1^\infty$ represent the cost of the claims and the gross risk premium rate c , the income. We, when nothing else is said, assume that $\{Z_k\}_1^\infty$ is i.i.d. and independent of N .

Usually, the distribution F of Z_k is assumed to be either *exponentially bounded* (see **Cramér–Lundberg Estimates**) or to belong to the class $\mathcal{S}$ of *subexponential distributions* (see **Heavy Tails in Insurance**). These classes of distributions are also referred to as *light tailed* and *heavy tailed*, respectively.

Definition 2 A distribution F on $[0, \infty)$ belongs to $\mathcal{S}$ if

$$\lim_{z \rightarrow \infty} \frac{1 - F^{2*}(z)}{1 - F(z)} = 2 \quad (8)$$

The Γ -distribution is a typical example of an exponentially bounded distribution, while the Pareto distribution and the lognormal distribution are subexponential. A class of exponentially distributed distributions of great interest is that of the phase-type distributions (see **Phase-type Distribution**).

It may very well be the case that a light-tailed F is too “kind” while an $F \in \mathcal{S}$ is too “dangerous”. Then it may be tempting to try to find some intermediate case with nice properties. $\mathcal{S}(\beta)$ is such a class:

Definition 3 A distribution F on $[0, \infty)$ belongs to the class $\mathcal{S}(\beta)$, $\beta \geq 0$, if

- (i) $\hat{h}(\beta) < \infty$;
- (ii) $\lim_{z \rightarrow \infty} (1 - F^{2*}(z))/(1 - F(z)) = c$,
 $0 < c < \infty$;
- (iii) $\lim_{z \rightarrow \infty} (1 - F(z + y))/(1 - F(z)) = e^{-\beta y}$

for all real y .

Embrechts [11] has shown that certain generalized inverse Gaussian distributions belong to $\mathcal{S}(\beta)$.

The classes $\mathcal{S}$ and $\mathcal{S}(\beta)$ were introduced by Chistyakov [5].

Sometimes, it may be natural to allow for dependence between $\{Z_k\}_1^\infty$ and N . As an example, consider the Markov-modulated Poisson process motioned in Example 3. Let $\{X_1, X_2, \dots, X_M\}$ be M independent risk processes, as in equation (1), where X_k has Poisson intensity λ_k , claim cost distribution F_k , and gross risk premium rate c_k . In automobile insurance, it is natural to allow the weather situation to have influence on both the intensity and the cost. The risk business X now follows X_k when $J = k$, that is, $dX(t) = dX_{J(t)}(t)$.

The generalization of a constant premium rate c mentioned above, may not be the most natural one. Examples of more relevant extensions of the premium rate within the risk model are given below:

1. The premiums may depend on the result of the risk business. It is natural to let the premium decrease when risk business increases and *vice versa*.
2. Inflation and interest may be included in the model. If the interest is higher than the inflation, then the premium decreases when risk business decreases and *vice versa*.
3. Part of the risk business may be risky investments (see **Ruin Models with Investment Income**).

References [8, 10] are very readable studies focusing mainly on generalizations (1) and (2).

Early studies of generalizations (1) and (2) are found in [9, 20], respectively.

The question of “fair” premiums for an individual policyholder is of utmost importance for a company (see **Actuarial Premium Principles and Credibility Theory**). The discussion in Example 1 about prior and posterior distributions of λ is related to credibility theory.

Solvency

Capital Requirements

Capital, most often, is the sum of contributed capital and retained earnings. In modern times, financial economics has developed a variety of other instruments to supply capital to companies. Capital is often referred to in the insurance industry as *surplus*. Whatever term is used to describe the concept (we shall here use the term *capital*), a primary concern is the amount of capital that must be held.

The amount of required capital will depend upon the methods used to determine policy liabilities within financial reporting since different methods provide varying degrees of conservatism that can be applied to offset risk and required capital. Therefore, a change in financial reporting may necessitate alteration of capital requirements.

Determination of required capital involves consideration of a number of factors including the time over which solvency is to be protected (the “time horizon”), the degree of probability to which future solvency is to be maintained, and the scope of threats to future solvency (the “risks”) to be considered in the calculation. The usual approach is to consider a variety of important risks; hence modern capital requirements are usually termed *risk based*.

The initial and historical approach to solvency and required capital is through ruin theory (*see Ruin Theory* and [8]). Here, the only source of risk considered is the insurance claims process. From a solvency perspective, the aim of the theory is to determine the amount of capital required to ensure that the probability of continued solvency (i.e., nonruin) up to some chosen time horizon is as high as desired. There are discrete and continuous time versions of the theory and the time horizon can be either finite or infinite. Ruin theory can definitely provide insight into the insurance process. However, its concentration on a single source of risk leads it to be most applicable to nonlife or general insurance and of much less use in life insurance (*see Life Insurance*) where financial risks play a much larger role. The theory is structured to calculate the probability of ruin given the initial available capital. The calculations are difficult and the theory has not often been applied in practice although it was

the basis for the first dynamic capital requirements created in Finland in the early 1940s.

An important advance came in the early 1980s with the availability of high-speed computers and the development of models of the insurance process that could be used to simulate an insurer’s financial progress. The leading work in this area was carried out in Finland by Pentikäinen and his colleagues [11]. To construct their model, this group first extended classical risk theory to include a number of significant variables, in addition to the claims process. This work is described in [12]. An extended, more modern, and readily available description of this approach can be found in [2].

Regulatory Approach to Solvency

Insurance regulators and supervisors are primarily charged with protecting the interests of policyholders and others holding contracts issued by insurance companies. They are clearly interested in insurers’ solvency. Historically, the emphasis in statutory financial reporting was on a conservative valuation of policy liabilities as a means of maintaining solvency. Although many jurisdictions required insurers to have a minimum amount of capital before being licensed to carry on the business of insurance, there were often no requirements that insurers had to maintain specific capital levels. In those jurisdictions where insurance companies were required to maintain capital of a uniform monetary amount, that amount usually did not vary by the size of the company, the nature of its portfolio of policies issued, its financial experience and condition, or its method of operation.

The earliest development of more modern risk-based capital requirements began in Finland in the 1940s; the determination of an insurer’s required capital was based upon ruin theory. The focus was upon excessively high claim frequency and severity. A second important step was the introduction, in the First Insurance Directive of the European Union, of a capital requirement for life insurance companies that was calculated in two parts: a fixed percentage of mathematical reserves and a smaller percentage of the net amount at risk. The portion related to mathematical reserves was meant to provide for credit and market risks related to the assets supporting these liabilities while the second portion was meant to provide for insurance (claims) risk.

Both the Finnish and the European innovations represent an effort to relate a company's capital requirement to the risks to which it is exposed. Further developments in this direction required a systematic study and listing of these sources of risk. The Committee on Valuation and Related Problems of the Society of Actuaries carried out one of the earliest such studies; its report was published in 1979 [4]. The committee suggested that risk could be categorized in three parts and that capital, or contingency reserves, could be provided for each part. The parts are C1, asset depreciation; C2, pricing inadequacy; and C3, interest-rate fluctuation (*see Bond and Term Structure Models*). In more modern terms, these would now be called C1, *credit risk*; C2, *insurance risk*; C3, *asset/liability mismatch risk*.

Work on the first modern risk-based capital requirement began in Canada in 1984, based upon the committee's categorization. By 1989, a test calculation had been established. This was subject to extensive field tests in the life insurance industry and became a regulatory requirement in 1992; it is known as the *Minimum Continuing Capital and Surplus Requirement* (MCCSR) [9]. A similar requirement was not established for Canadian property and casualty (general) insurers until 2002 [10]. In the United States, following an increase in the number of failures of insurance companies due to economic experience in the late 1980s and early 1990s, the National Association of Insurance Commissioners (NAIC) began work on a similar capital requirement for life insurers. The structure of the NAIC formula, known widely as *risk-based capital* (RBC), follows the committee's categorization and was quite similar to the Canadian formulation. Both national requirements have evolved independently; although they remain similar, there are significant differences between them. Shortly after it established the life insurance company formula, the NAIC introduced a capital requirement for property and casualty insurers. It has since introduced a separate requirement for health insurers.

A number of other jurisdictions have adopted regulatory capital requirements for insurance companies. These tend to follow the North American formulations.

The development of the more comprehensive insurance regulatory capital requirements was parallel to but independent of the similar development of a requirement for banks under the Basel Accord (*see*

Regulatory Capital). Although these developments occurred independently, future prospects are that the banking and insurance capital requirements will eventually have a strong influence on each other. This is due to two factors: the recent emergence of large financial conglomerates or groups that engage in both banking and insurance, and the trend in many countries to form integrated regulators/supervisors that oversee both industries. The formerly distinct cultures of banking and insurance are thereby influencing each other both in business and government.

Developments in Regulatory Capital since 2000

The first decade of the twenty-first century has seen a great deal of activity and advances in capital requirements and solvency. This is due to an increased appreciation of the risks faced by financial institutions, a heightened awareness of their need for capital, the emergence of the discipline of enterprise risk management, the drive to establish uniform international financial reporting standards (IFRS) by the International Accounting Standards Board (IASB), and regulatory moves, on a worldwide basis, by the International Association of Insurance Supervisors (IAIS) and in Europe by the European Union, to establish international supervisory standards.

Since its formation in the middle 1980s, the IAIS has been developing a series of papers on best practices for insurance supervisors. Solvency regulation and supervision has naturally been a major focus of IAIS activities [6]. In preparation for the development of papers on capital requirements, the IAIS asked the International Actuarial Association (IAA) for technical assistance. In 2002, the IAA formed its Insurer Solvency Assessment Working Party, which produced its report [5] in 2004. The IAIS continues to develop its series of papers on this topic.

The IAA report has become the conceptual basis for much of the recent work on insurance capital requirements. This is particularly the case with respect to work being done in Europe under the Solvency II project. The results of this project, a Europe-wide unified approach to insurance financial reporting and solvency supervision, is expected to come into effect in 2011. At the time of writing, the exact form of the Solvency II capital requirements has not been

fixed. The Committee of European Insurance and Occupational Pension Supervisors (CEIOPS), which has been charged with development of these requirements, has been conducting a series of qualitative impact studies that seek industry tests of proposed formulations of these requirements.

Advanced Approaches and Internal Models

An important feature of the Solvency II proposed capital requirement is the availability of an advanced approach for technically advanced insurers. Under this approach, insurers will determine their required capital using internal models that have been approved by supervisors. To be permitted to adopt this approach, insurers must satisfy a number of conditions involving not only the model itself but also the quality of implementation and execution of the insurer's risk management program. In particular, insurers will be required to satisfy a "use test" and show that the internal model is used within the firm's operations. This test is intended to assure that insurers have sufficient confidence in the quality and accuracy of their models.

Internal models have been used as part of the MCCR and RBC requirements in Canada and the United States, respectively. In particular, they have been applied to the liability valuation and capital requirements for certain financial guarantees that insurers offer in connection with certain (variable annuity) investment contracts. They have also been used for banking capital requirements under the Basel Accord, initially with respect to market risk in the trading book and more lately, under Basel II [1], with respect to credit and operational risks (*see Regulatory Capital and Operational Risk*).

Use of an advanced approach is likely to often produce lower capital requirements than would be produced by a standard and generally conservative regulatory formula. Supervisors justify accepting reduced capital because they require the financial institution to have a strong risk management program before being allowed to adopt an advanced approach.

The use of internal models was anticipated in the IAA report [5]. More recently the IAIS has published a standard and a paper on internal models, primarily directed to supervisors [7]. The IAA is preparing a companion paper directed to practitioners who construct and operate these models.

Beyond Regulatory Capital Requirements

The supervision of solvency extends beyond regulatory capital requirements. Many supervisors have adopted a structure that resembles one laid out in Basel II. The structure is described in terms of three Pillars: Pillar 1—Minimum Capital Requirements, Pillar 2—Supervisory Review Process, and Pillar 3—Market Discipline. The discussion heretofore has centered on Pillar 1. These are described in detail in [1].

An interesting feature of Pillar 2 involves the assessment of an insurer's capital adequacy, extending beyond minimum Pillar 1 requirements. An early and trail-blazing approach has been taken by the Financial Services Authority (FSA) of the United Kingdom with the introduction of individual capital adequacy assessment [3]. Each insurer is expected to have the ability to assess its own view of its capital needs, its economic capital. This assessment will usually be made with an internal model. The FSA may ask insurers to submit their models for examination. This is not a formal model approval. Rather, the FSA examines the model to ensure it covers all significant sources of risk for the particular firm and provides its views to the firm as individual capital guidance.

The third Pillar is based upon the notion that market discipline will act to force an insurer to operate its business in a sound and prudential manner, thus stimulating a convergence between the interests of the firm, its policyholders, and its supervisors. Supervisors' primary activity in this area centers on encouraging and/or requiring firms to publicly disclose information that is required by policyholders and investors to assess the firm's condition.

Solvency, Risk Management, and Economic Capital

Much of the thrust for improved capital requirements and risk management has come from the regulatory/supervisory sector. However, many insurers, particularly the larger and multinational firms, have undertaken their own initiatives to develop economic capital requirements and to apply them as an integral part of their business operations. In addition, these firms have adopted many ideas and practices from the growing field of enterprise risk management. The role of the chief risk officer has gained considerable

importance within these insurers. Many of the responsibilities that were formally assigned to the company actuary have been assumed by the chief risk officer. Economic capital and risk management have become the firm's operational tools to measure and control the risk of its own insolvency.

ALLAN BRENDER

Cramér's Theorem

Let $X, X_1, X_2, \dots$ be independent and identically distributed (i.i.d.) random variables with partial sums $S_n = \sum_{k=1}^n X_k$ and empirical means $\hat{S}_n = n^{-1} S_n$ for $n = 1, 2, \dots$. Assuming a finite mean $\mu = E[X]$, by the law of large numbers, it holds for every $x > \mu$ that

$$\lim_{n \rightarrow \infty} P(\hat{S}_n > x) = 0 \quad (1)$$

Cramér's theorem refines this result by identifying an exact exponential decay rate of the small probability in equation (1). Note that the central limit theorem cannot, in general, capture this subtle decay rate because the central limit theorem focuses on average-sized fluctuations while the rare event $(\hat{S}_n > x)$ is mainly determined by large values of the random variables $X_1, \dots, X_n$.

Study of the probability of such a rare event has important applications in insurance and finance. For example, in insurance context, we may understand the random variables $X_1, \dots, X_n$ as respective claim amounts of n policy holders during a time period or of a single policy holder during n time periods. The event $(\hat{S}_n > x)$ with $x \geq \mu + \delta$, where $\delta > 0$ is interpreted as the safety loading, describes a critical situation that the insurance company loses money. To make sure that the probability of this rare event is sufficiently small, we need to determine what value of δ is appropriate. A good approximation for the probability $P(\hat{S}_n > x)$ enables us to get a simple yet powerful solution to this problem.

Let us take another example from financial risk management. Denote by $Q_\alpha[S_n]$ and $\text{CTE}_\alpha[S_n]$, respectively, the quantile (value at risk) and conditional tail expectation of the sum S_n of n risk variables, where $\alpha \in (0, 1)$ represents the confidence level, usually chosen to be close to 1 (see **Value-at-Risk** and **Expected Shortfall**). By definition,

$$Q_\alpha[S_n] = \inf\{y : P(S_n > y) \leq 1 - \alpha\} \quad (2)$$

and

$$\begin{aligned} \text{CTE}_\alpha[S_n] &= E[S_n | S_n > Q_\alpha[S_n]] \\ &= Q_\alpha[S_n] + \frac{\int_{Q_\alpha[S_n]}^{\infty} P(S_n > y) dy}{P(S_n > Q_\alpha[S_n])} \end{aligned} \quad (3)$$

Hence, an efficient approximation for the probability in equation (1) is desired for calculation of both $Q_\alpha[S_n]$ and $\text{CTE}_\alpha[S_n]$.

Define the cumulant generating function of X as

$$\Lambda(\lambda) = \ln E[e^{\lambda X}], \quad \lambda \in \mathbb{R} \quad (4)$$

Note that $\Lambda(0) = 0$ and $-\infty < \Lambda(\lambda) \leq \infty$ for all $\lambda \in \mathbb{R}$. Further define the Fenchel–Legendre transform of $\Lambda(\cdot)$ as

$$\Lambda^*(x) = \sup_{\lambda \in \mathbb{R}} \{\lambda x - \Lambda(\lambda)\}, \quad x \in \mathbb{R} \quad (5)$$

It can be shown that both $\Lambda(\cdot)$ and $\Lambda^*(\cdot)$ are convex (but not necessarily strictly convex) functions on $\mathbb{R}$ and that $\Lambda^*(\cdot)$ is lower semicontinuous (i.e., $\Lambda^*(\cdot)$ takes values in $[0, \infty]$ and is such that, for every $y \in [0, \infty)$, the level set $\{x : \Lambda^*(x) \leq y\}$ is closed).

The following are some concrete and easily verifiable examples for $\Lambda^*(\cdot)$ (see, e.g., page 35 of [3]):

1. If X follows a Poisson distribution with mean $\theta > 0$ then $\Lambda^*(x) = \theta - x + x \ln \frac{x}{\theta}$ for $x \geq 0$ and $\Lambda^*(x) = \infty$ otherwise.
2. If X follows a Bernoulli distribution with success probability $p \in (0, 1)$ then $\Lambda^*(x) = x \ln \frac{x}{p} + (1-x) \ln \frac{1-x}{1-p}$ for $x \in [0, 1]$ and $\Lambda^*(x) = \infty$ otherwise.
3. If X follows an exponential distribution with mean $1/\theta$ then $\Lambda^*(x) = \theta x - 1 - \ln(\theta x)$ for $x > 0$ and $\Lambda^*(x) = \infty$ otherwise.
4. If X follows a normal distribution with mean μ and variance σ^2 then $\Lambda^*(x) = \frac{(x - \mu)^2}{2\sigma^2}$.

For a Borel set Γ , denote by $\bar{\Gamma}$ and $\bar{\Gamma}$ its interior and closure, respectively. Throughout, $\inf \emptyset = \infty$, by convention.

Cramér's Theorem For every Borel set Γ with nonempty interior,

$$\begin{aligned} -\inf_{x \in \bar{\Gamma}} \Lambda^*(x) &\leq \liminf_{n \rightarrow \infty} \frac{1}{n} \ln P(\hat{S}_n \in \Gamma) \\ &\leq \limsup_{n \rightarrow \infty} \frac{1}{n} \ln P(\hat{S}_n \in \Gamma) \\ &\leq -\inf_{x \in \bar{\Gamma}} \Lambda^*(x) \end{aligned} \quad (6)$$

A sequence of probability measures, $\{P_n\}$, is said to satisfy the large deviation principle (see **Large Deviations**) with a rate function $I(\cdot)$ if, for every Borel set Γ ,

$$\begin{aligned} -\inf_{x \in \bar{\Gamma}} I(x) &\leq \liminf_{n \rightarrow \infty} \frac{1}{n} \ln P_n(\Gamma) \\ &\leq \limsup_{n \rightarrow \infty} \frac{1}{n} \ln P_n(\Gamma) \leq -\inf_{x \in \bar{\Gamma}} I(x) \end{aligned} \quad (7)$$

Thus, Cramér's theorem shows that the probability laws of the empirical means $\hat{S}_n$ satisfy the large deviation principle with rate function $\Lambda^*(\cdot)$ (see **Large Deviations**).

Note that Cramér's theorem does not require $\Lambda(\lambda) < \infty$ for all $\lambda \in \mathbb{R}$. It is applicable even when the mean of X does not exist. For $\mu \in \bar{\Gamma}$, Cramér's theorem does not contribute because both sides of equation (6) turn out to be zero. If $\inf_{x \in \bar{\Gamma}} \Lambda^*(x) = \inf_{x \in \bar{\Gamma}} \Lambda^*(x)$, as is often the case in applications, then

$$\lim_{n \rightarrow \infty} \frac{1}{n} \ln P(\hat{S}_n \in \Gamma) = -\inf_{x \in \bar{\Gamma}} \Lambda^*(x) \quad (8)$$

or, equivalently,

$$P(\hat{S}_n \in \Gamma) = \exp \left\{ -n \left(\inf_{x \in \bar{\Gamma}} \Lambda^*(x) + o(1) \right) \right\} \quad (9)$$

where $o(1)$ tends to 0 as $n \rightarrow \infty$. It can be shown that, for every real number y ,

$$\lim_{n \rightarrow \infty} \frac{1}{n} \ln P(\hat{S}_n \geq y) = -\inf_{x \geq y} \Lambda^*(x) \quad (10)$$

see, for example, Corollary 2.2.19 of [3].

The first statement of Cramér's theorem for distributions possessing densities was given by Cramér [2], who applied it to model the insurance business (see **Cramér–Lundberg Estimates**). This is the first rigorous result concerning large deviations and is viewed as the historical starting point of large deviation theory. An extension to general distributions was done by Chernoff [1]. Cramér's theorem is also often cited as the Cramér–Chernoff theorem in the literature of large deviation theory.

Various versions of Cramér's theorem have been included in many monographs in large deviation theory. This most general version of Cramér's theorem is due to [3]. Textbook treatments of Cramér's theorem can be found in [6, 16], and [10], among others.

A similar result for the empirical means of i.i.d. random vectors in $\mathbb{R}^d$ has been established. A further extension to dependent, not necessarily identically distributed, random vectors in $\mathbb{R}^d$ leads to the Gärtner–Ellis theorem.

Large Deviations Without Cramér's Condition

Note that if $\Lambda(\lambda) = \infty$ for all $\lambda \neq 0$, then $\Lambda^*(x) = 0$ for all $x \in \mathbb{R}$ and consequently equation (7) gives a trivial approximation

$$\lim_{n \rightarrow \infty} \frac{1}{n} \ln P(\hat{S}_n \in \Gamma) = 0 \quad (11)$$

Similarly, if $\Lambda(\lambda) = \infty$ for all $\lambda > 0$, then $\Lambda^*(x) = 0$ for all $x \geq \mu$ and, in this case, Cramér's theorem leads to equation (11) with $\Gamma = [\mu, \infty)$, while if $\Lambda(\lambda) = \infty$ for all $\lambda < 0$ then $\Lambda^*(x) = 0$ for all $x \leq \mu$ and in this case Cramér's theorem leads to equation (11) with $\Gamma = (-\infty, \mu]$. To avoid such trivialities, it is necessary to assume $\Lambda(\lambda) < \infty$ in a neighborhood of $\lambda = 0$, which is usually referred to as *Cramér's condition*.

Study of large deviations for heavy-tailed random variables for which Cramér's condition is violated forms another important part of large deviation theory. The concept of subexponentiality plays a central role during the study in this direction. By definition, the common distribution of i.i.d. random variables $X, X_1, X_2, \dots$ is said to be subexponential (on the right)

if the relation

$$\lim_{x \rightarrow \infty} \frac{P\left(\sum_{k=1}^n X_k^+ > x\right)}{P(X^+ > x)} = n \quad (12)$$

holds for some (or, equivalently, for all) $n = 2, 3, \dots$, where $X^+ = \max\{X, 0\}$ (see **Heavy Tails in Insurance**). We remark that many popular distributions such as Pareto, lognormal, and heavy-tailed Weibull distributions are subexponential; see, for example, [5]. The very definition of subexponentiality opens a natural way to establish

$$\lim_{n \rightarrow \infty} \sup_{x \geq x_n} \left| \frac{P(S_n > x)}{nP(X > x)} - 1 \right| = 0 \quad (13)$$

for appropriate constants x_n serving as a threshold. The uniform asymptotic relation (13) is at the core of the mainstream study of large deviations in the presence of heavy tails. We usually say that results like equation (13) give precise asymptotics for large deviations while results like equations (6) and (10) give rough asymptotics for large deviations.

Pioneering works in the study of precise large deviations include [12, 13] and [7–9]. Overviews are available in [14] and [11], the latter of which contains a table summarizing choices of the threshold sequence $\{x_n\}$ in equation (13) for most subexponential distributions. Some recent developments of precise large deviations can be found in [15] and [4], among others.

Accumulated Claims

For measuring *operational risk* (see **Operational Risk**) or the risk of an insurance contract or an insurance portfolio, one has to find “good” models for the losses of the contract. These models need to be simple in order to be able to get desired answers but complicated enough to reflect the “real” situation. To achieve this goal, there are two different approaches: one approach is to model the number of claims and the individual claim sizes and the other is to model the distribution of the accumulated claim sizes directly. We consider the first approach in the second section and the second approach in the third section. In the fourth section, we discuss numerical methods to calculate the distribution function.

Compound Models

The most natural way to model the accumulated claims distribution is the distribution of a random sum

$$S = \sum_{k=1}^N Y_k \quad (1)$$

where $N \in \{0, 1, \dots\}$ is the (random) number of claims and Y_k is the (random) size of the k th claim. Here, we make the convention $\sum_{k=1}^0 Y_k = 0$. In a portfolio where claims do not occur simultaneously, one can assume that N and $\{Y_k\}$ are independent and that $\{Y_k\}$ are independent and identically distributed (i.i.d.). If claims occur simultaneously—as, for instance, claims caused by natural catastrophes—one has to consider Y_k as the accumulated claim from an event. The distribution of S is then called a *compound distribution* (see **Ruin Theory; Insurance Risk Models**).

One often needs some characteristics of the distribution of S . By conditioning on N , one finds

$$\mathbb{E}[S] = \mathbb{E}[N]\mathbb{E}[Y] \quad (2)$$

$$\text{Var}[S] = \text{Var}[N]\mathbb{E}[Y]^2 + \text{Var}[Y]\mathbb{E}[N] \quad (3)$$

$$\mathbb{E}[e^{rS}] = \mathbb{E}[\exp\{N \log \mathbb{E}[e^{rY}]\}] \quad (4)$$

We see that the characteristics can be easily calculated from the corresponding quantities for N and Y .

Let $p_k = \mathbb{P}[N = k]$. Popular models for N are the binomial distribution $p_k = \binom{n}{k} q^k (1-q)^{n-k}$, $n \in \mathbb{N}$, $q \in (0, 1)$; the Poisson distribution $p_k = e^{-\lambda} \lambda^k / k!$, $\lambda > 0$; the negative binomial distribution $p_k = \binom{\alpha + k - 1}{k} q^\alpha (1-q)^k$, $\alpha > 0$, $q \in (0, 1)$; and the logistic distribution $p_k = -q^{n+1} / [(n+1) \log(1-q)]$, $q \in (0, 1)$.

The Poisson distribution appears as a limit. Suppose that there are m independent individual contracts where a claim occurs with probability $q^{(j)}$. The average number of claims is approximately $\lambda = \sum_{j=1}^m q^{(j)}$. If now $m \rightarrow \infty$ such that λ remains constant and $\sum_{j=1}^m (q^{(j)})^2 \rightarrow 0$, then the number of claims converges to a Poisson distribution with parameter λ .

The compound Poisson model has a few more nice properties. Suppose that there are m portfolios $S^{(j)}$ modeled as compound Poisson with parameter $\lambda^{(j)}$ and the distribution $G^{(j)}(y)$ of the increments. Then $S = \sum_{j=1}^m S^{(j)}$ has a compound Poisson distribution with parameter $\lambda = \sum_{j=1}^m \lambda^{(j)}$ and distribution of the increments

$$G(y) = \sum_{j=1}^m \lambda^{-1} \lambda^{(j)} G^{(j)}(y) \quad (5)$$

Conversely, if S has a compound Poisson distribution and $B^{(j)}$ are sets such that $B^{(i)} \cap B^{(j)} = \emptyset$ for $i \neq j$, then $S^{(j)} = \sum_{k=1}^N Y_k \mathbb{I}_{Y_k \in B^{(j)}}$ are independent and compound Poisson distributed with parameter $\lambda^{(j)} = \lambda \mathbb{P}[Y \in B^{(j)}]$ and $Y_k^{(j)}$ has the distribution $\mathbb{P}[Y \in \cdot \mid Y \in B^{(j)}]$.

Easy treatable models are also mixed Poisson models, where $\Lambda \geq 0$ is a random variable, and N conditioned on Λ has a Poisson distribution with parameter Λ . One finds that

$$\mathbb{E}[N] = \mathbb{E}[\Lambda] \quad (6)$$

$$\text{Var}[N] = \text{Var}[\Lambda] + \mathbb{E}[\Lambda] \quad (7)$$

$$\mathbb{E}[e^{rN}] = \mathbb{E}[\exp\{\Lambda(e^r - 1)\}] \quad (8)$$

For example, if Λ follows a gamma distribution, which means that Λ has the density $\beta^\gamma x^{\gamma-1} e^{-\beta x} \mathbb{I}_{x>0} / \Gamma(\gamma)$, then N has a negative binomial distribution with $\alpha = \gamma$ and $q = \beta / (\beta + 1)$.

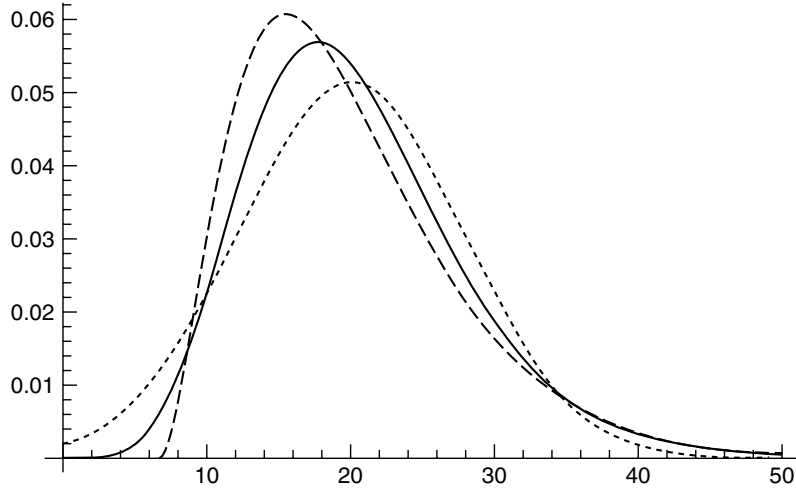

Figure 1 Densities of S (solid line), its normal approximation (dotted line), and its translated gamma approximation (dashed line)

Further risk models and details can be found in [1, 3, 4, 7, 9]. Applications to operational risk are described in [2, 5, 6].

Approximations

The calculation of the distribution of a compound sum is in general not possible. It involves n -fold convolutions, that is, n -fold integrals, which numerically is a problem. One, therefore, has to use approximations to the aggregate claims distribution. Let us denote by $\mu_k = \mathbb{E}[S^k]$ the moments of S , by $\sigma^2 = \mu_2 - \mu_1^2$ the variance, and by $\beta = \mathbb{E}[(S - \mu)^3]\sigma^{-3/2}$ the coefficient of skewness.

The *normal approximation* is the normal distribution with the same mean and variance as S . This approximation usually does not fit well because it does not take care of the skewness.

An approximation that usually works well is the *translated gamma approximation*. Let $\gamma = 4\beta^{-2}$, $\alpha = 2/(\beta\sigma)$, and $k = \mu - \gamma/\alpha$. Let Z be a gamma-distributed random variable with parameters γ and α . Then $Z + k$ has the same first three moments as S . That three moments are matched is also a reason for the good fit.

As an example we consider a compound Poisson distribution with $\lambda = 20$ and Pareto-distributed claim sizes with mean 1 and variance 2, that is,

$\mathbb{P}[Y > y] = (3/(3 + y))^4$. Figure 1 shows the densities of the exact distribution and its normal and translated gamma approximations. Both approximations do not fit well close to the mean value 20, but for risk management this region is not very interesting. We can see that in the right tail the normal approximation underestimates the true density considerably, whereas the fit in the tail of the translated gamma approximation is quite good.

Further possibilities for approximations are Edgeworth expansions, saddle point approximations, or the normal power approximation, [3, 4, 7, 9].

Panjer Recursion

Suppose that $Y_i > 0$ takes values in $\mathbb{N}$. Then also S takes values in $\mathbb{N}$. If we denote by $f_k = \mathbb{P}[Y = k]$ and $f_k^{*n} = \mathbb{P}[Y_1 + \dots + Y_n = k]$, then $g_k = \mathbb{P}[S = k]$ can be calculated by $g_0 = p_0$ and $g_n = \sum_{k=1}^n p_k f_n^{*k}$. The convolutions are obtained recursively: $f_k^{*(n+1)} = \sum_{\ell=1}^{k-1} f_\ell^{*n} f_{k-\ell}$, where $f_\ell^{*1} = f_\ell$. The problem is that numerous calculations have to be executed, which makes the procedure slow.

A faster procedure can be found if for $r \geq 1$

$$p_r = \left(a + \frac{b}{r}\right) p_{r-1} \quad (9)$$

for some constants a, b . It turns out that the distribution of N must be binomial ($a < 0$, $-b/a \in \mathbb{N}$), Poisson ($a = 0$, $b > 0$), or negative binomial ($a \in (0, 1)$, $a + b > 0$). In these cases, we have $g_0 = p_0$ and recursively

$$g_r = \sum_{k=1}^r \left(a + \frac{bk}{r} \right) f_k g_{r-k} \quad (10)$$

The method is fast and is also stable for the compound Poisson and the compound negative binomial distributions. This method goes back to Panjer [8].

Generalizations of formula (10) are treated for the case where $f_0 > 0$ or the case where the recursion (9) holds for $r \geq \ell > 1$ [4, 10–12].

HANSPETER SCHMIDLI

Gerber–Shiu Function

Risk theory studies **insurance risk models** that describe the uncertainty associated with the claims recorded by an insurance company for the losses incurred by its policy holders. From premium and investment income, insurers set aside funds (surplus) to cover such losses. Ruin theory studies the fluctuations of these surplus processes. Classical problems include ruin (low) and dividend (high) barrier hitting times (see [5]).

In the last decade, the expected discounted penalty function, proposed by Gerber and Shiu, has unified the treatment of the joint distribution of the time to ruin, the surplus just prior to ruin, and the deficit at ruin. This article centers on this expected discounted penalty function, commonly called the *Gerber–Shiu (G–S) function* in the actuarial literature.

The G–S function is somewhat akin to an expected discounted payoff function for financial instruments. A brief description of its general features is given here, together with references that discuss details, generalizations, and applications to insurance and finance.

Introduction

Risk theory models describe the uncertainty associated with the claims recorded by an insurance company. The aggregate claims up to time t ,

$$S(t) = X_1 + \cdots + X_{N(t)} = \sum_{i=1}^{N(t)} X_i, \quad t \geq 0 \quad (1)$$

(with $S(t) = 0$ if $N(t) = 0$) forms a random process of interest in **Insurance Risk Model**. It combines the two sources of uncertainty about the portfolio—the claim frequency and severity. The collection $\{S(t)\}_{t \geq 0}$ is called the *aggregate claims process*, see [9, Chapters 6, 9].

Another important insurance process is the accumulated surplus at t :

$$U(t) = u + ct - S(t) = u + ct - \sum_{i=1}^{N(t)} X_i, \quad t > 0 \quad (2)$$

where $U(0) = u \geq 0$ is the initial surplus at time 0. Here c denotes the aggregate premium amount

charged per unit time by the company to its portfolio policy holders, and $S(t)$ is given by equation (1).

Ruin Theory

The central focus of classical **Ruin Theory** is the time of ruin

$$T = \inf\{t > 0; U(t) < 0\} \quad (3)$$

when the surplus falls below zero for the first time. Depending on the aggregate claims model $S(t)$, if $c > \mathbb{E}[S(1)]$, the time of ruin T may be a defective random variable, with $\Psi(u) = \mathbb{P}\{T < \infty\} < 1$. This $\Psi(u)$ is called the *probability of ultimate ruin*, whereas the (possibly defective) distribution function of T , $\Psi(u; t) = \mathbb{P}\{T < t\}$, is called the *finite-time ruin probability* [1].

The expected discounted penalty function, introduced by Gerber and Shiu in [6], captures the joint distribution of three random variables related to ruin; the time of ruin T , the surplus immediately prior to ruin $U(T^-)$, a **Solvency** early warning, and the severity of the deficit at ruin $|U(T)|$, a recovery test measure. Also called the *Gerber–Shiu (G–S) function*, the expected discounted penalty function is defined as

$$\begin{aligned} \Phi_\delta(u) &= \mathbb{E} \left[e^{-\delta T} w \left(U(T^-), |U(T)| \right) I(T < \infty) \mid U(0) = u \right] \end{aligned} \quad (4)$$

where δ is the discount rate and w is a known penalty function, representing the cost to the insurer, at the time of ruin, of a surplus $U(T^-)$ prior to ruin and of a deficit $|U(T)|$ at ruin. The indicator function $I(T < \infty)$ applies the penalty only if ruin occurs.

Table 1 lists some interesting special choices of the penalty function w .

The G–S function was first derived in [6] for the classical Poisson risk model, in which $S(t)$ in equation (1) is a compound Poisson $(\lambda; F_X)$ process. Gerber and Shiu show that Φ_δ satisfies a defective renewal equation

$$\begin{aligned} \Phi_\delta(u) &= \frac{\lambda}{c} \int_0^u \Phi_\delta(u-x) \int_x^\infty e^{-\rho(y-x)} dF_X(y) dx \\ &\quad + \frac{\lambda}{c} e^{\rho u} \int_u^\infty e^{-\rho x} \int_x^\infty w(x, y-x) dF_X(y) dx \end{aligned} \quad (5)$$

Table 1 G–S function $\Phi_\delta(u)$ for different penalty functions w

δ	$w(x, y)$	Special case of the G–S function $\Phi_\delta(u)$
$\delta > 0$	e^{-tx-sy}	Trivariate Laplace transform of T , $U(T^-)$ and $ U(T) $
$\delta > 0$	1	the Laplace transform of T
$\delta = 0$	$x^m y^n$	Joint moments of $U(T^-)$ and $ U(T) $
$\delta = 0$	$I(x + y \leq z)$	(defective) distribution of ruin-causing claim at z
$\delta = 0$	$I(x \leq z, y \leq z')$	joint distribution of $U(T^-)$ and $ U(T) $ at (z, z')
$\delta = 0$	1	The probability of ultimate ruin $\Psi(u)$

where ρ is the unique nonnegative solution of Lundberg’s equation

$$\lambda + \delta - c\rho = \lambda \hat{F}_X(\rho) \quad (6)$$

and $\hat{F}_X(s) = \int_0^\infty e^{-sx} dF_X(x)$ is the Laplace–Stieltjes transform of F_X .

The solution of equation (5) can be expressed as an infinite series of convolutions $\Phi_\delta(u) = h * \sum_k g^{*k}(u)$, for given auxiliary functions g and h . This result extends to more general risk processes, including the Sparre Andersen (compound renewal) model [10], discounting of claims [2, 3], Lévy risk processes [4], or the Markov-modulated risk model [11].

Applications to Finance

The G–S function has been used also to analyze some financial instruments, such as several types of perpetual American options [7, 8]. As pointed out in these references, the pricing of perpetual options is related to the valuation of equity indexed annuities (EIA), hence the G–S function can help in analyzing the financial guarantee embedded in an EIA.

Current research work on G–S functions and extensions to financial instruments includes the valuation of contingent claims and the study of the optimal stopping time to exercise an option.

ALEJANDRO BALBAS & JOSE GARRIDO

Ruin Models with Investment Income

The problem of ruin has a long history in risk theory, going back to Lundberg [13]. Initially the assumption was that companies do not earn any investment return on their capital. The first attempt to incorporate investment incomes was undertaken by Segerdahl [19]. Segerdahl's assumption was that capital earns interest at a fixed rate r . This model was further elaborated in [8, 11], and it remains very popular even today. Then inspired by ideas from mathematical finance, in [14] a model was suggested where capital is allowed to be invested in risky assets. Before presenting this model, we refer the reader to [16] for a more extensive survey, including several topics not covered here.

To make the ideas transparent, we introduce the risk process by means of two basic processes, that is,

- a basic risk process P with $P_0 = 0$ and
- a return on investment-generating process R with $R_0 = 0$.

If P and R belong to the rather general class of semimartingales, we can define the risk process as

$$Y_t = y + P_t + \int_0^t Y_{s-} dR_s \quad (1)$$

so that $Y_0 = y$. The solution of this equation is

$$Y_t = e^{\tilde{R}_t} \left(y + \int_0^t e^{-\tilde{R}_s} dP_s \right) \quad (2)$$

where $\tilde{R} = \log \mathcal{E}(R)$ is the logarithm of the Doléans–Dade exponential of R , that is, $V_t = \mathcal{E}(R)_t$ satisfies the equations $dV_t = V_{t-} dR_t$ and $V_0 = 1$.

In this article, it is assumed that P and R are of the following forms:

$$P_t = pt + \sigma_P W_{P,t} - \sum_{i=1}^{N_t} S_i \quad (3)$$

$$R_t = rt + \sigma_R W_{R,t} \quad (4)$$

where W_P and W_R are Brownian motions, N is a Poisson process with rate λ , and $\{S_i\}$ are nonnegative independent and identically distributed (i.i.d.) random

variables with distribution function F . Furthermore, W_P , W_R , N , and $\{S_i\}$ are all independent. The idea is that p is the premium rate, $\{S_i\}$ are claims, while W_P represents fluctuations in premium income and maybe also small claims. The return on investment-generating process R is the standard Black–Scholes return process. With these assumptions, Y becomes a homogeneous, strong Markov process, a fact that allows us to draw on the vast literature on Markov processes. In addition, $\tilde{R}_t = R_t - \frac{1}{2}\sigma_R^2 t = (r - \frac{1}{2}\sigma_R^2)t + \sigma_R W_{R,t}$.

The time of ruin is defined as $T = \inf\{t : Y_t < 0\}$, with $T = \infty$ if Y stays positive. The probability of ruin in finite *versus* infinite time is then defined as

$$\begin{aligned} \psi(t, y) &= P(T \leq t | Y_0 = y) \quad \text{and} \\ \psi(y) &= P(T < \infty | Y_0 = y) \end{aligned} \quad (5)$$

Mathematically, $\psi(y)$ is the easiest, and probably as a consequence, it has by far been the most popular in the literature.

A more general concept that also allows for problems relating to the time of ruin, the size of the deficit at ruin, or the surplus immediately before ruin is the Gerber–Shiu penalty function [9]. It is given as

$$\Phi_\alpha(y) = E[g(Y_{T-}, |Y_T|)e^{-\alpha T} 1_{\{T < \infty\}} | Y_0 = y] \quad (6)$$

where g is a nonnegative function and $\alpha \geq 0$. Various choices of g and α allow for the computation of many interesting quantities related to ruin [4].

Some General Results

It is shown in [15] that under weak assumptions, $\psi(y) < 1$ if $r > \frac{1}{2}\sigma_R^2$ (equivalence when $\sigma_R^2 > 0$), and in this case it is proved in [10] that under some weak additional assumptions, ψ is twice continuously differentiable and is a solution of the equation,

$$G\psi(y) = -\lambda \bar{F}(y) \quad (7)$$

with boundary conditions

$$\lim_{y \rightarrow \infty} \psi(y) = 0 \quad \text{and} \quad \psi(0) = 1 \quad \text{if} \quad \sigma_P > 0 \quad (8)$$

Here G is the integro-differential operator

$$Gh(y) = \frac{1}{2}(\sigma_P^2 + \sigma_R^2 y^2)h''(y) + (p + ry)h'(y) + \lambda \int_0^y h(y-x)dF(x) - \lambda h(y) \quad (9)$$

and $\bar{F}(y) = 1 - F(y)$. Sometimes it is more convenient to work with the survival probability $\phi(y) = 1 - \psi(y)$, in which case equation (2) becomes $G\phi(y) = 0$. It is shown in [4] that the Gerber–Shiu penalty function satisfies an equation similar to equation (2).

Following ideas from [11], it was shown in [14] that the ruin probability can be written as

$$\psi(y) = \frac{H(-y)}{E[H(-Y_T)|T < \infty]} \quad (10)$$

where H is the distribution function of the perpetuity

$$X = \int_0^\infty e^{-\left(r - \frac{1}{2}\sigma_R^2\right)t + \sigma_R W_{R,t}} dP_t \quad (11)$$

Corresponding to equation (2), the finite time ruin probability $\psi(t, y)$ should be the solution to the partial integro-differential equation

$$-\frac{\partial}{\partial t}\psi(t, y) + G\psi(t, y) = -\lambda\bar{F}(y) \quad (12)$$

with the additional boundary condition $\psi(0, y) = 1_{\{y < 0\}}$. Here, the operator G acts on the y variable.

Analytical and Numerical Solutions

Since most analytical results are for the infinite time horizon, we start with this case. When $\lambda = 0$, the process is a pure diffusion process and the problem becomes rather easy. A solution can be found in [14]. When $\lambda > 0$, things become markedly more complex, and analytical solutions can be obtained only in a few rather simple cases. In addition, several of these solutions are very complicated. In all known solutions, it is assumed that $\sigma_R = 0$, so in the sequel we shall therefore tacitly let $\sigma_R = 0$.

We have already mentioned Segerdahl's classical work when $\sigma_P = 0$ and claim sizes are exponentially distributed. In [17], these solutions were extended to the case where claims are mixtures of two exponential

distributions, as well as to the case where they are Erlang (2) distributed. Extensions beyond that seem very difficult though. In [17], the case with $\sigma_P > 0$ and claims exponentially distributed was also solved. In [5], rather explicit expressions for the Gerber–Shiu penalty function are given for the case where $\sigma_P = 0$ and claims are exponentially distributed.

In the finite time horizon case, analytical solutions are hard to come by. In [1], a recursion for the survival probability $\phi(t, y)$ when $\lambda = kr$ for some positive integer k is provided. This recursion is solved and exact solutions are given for $k = 1$ and $k = 2$.

The issue of computing numerical values has received comparatively little attention. In [18], using integration by parts on the equation $G\phi(y) = 0$, this equation was turned into a Volterra integral equation and methods from numerical analysis were used to solve this numerically. In the finite time case, several methods have been proposed when $\sigma_P = \sigma_R = 0$; see, for example [3, 6]. These methods are rather intuitive in nature and are not based on any particular known procedure from numerical analysis. Their efficiency is, therefore, slightly low, but as a bonus they provide upper and lower bounds.

An alternative to traditional numerical methods is the Monte Carlo simulation, which is particularly well suited for finite time ruin problems. For infinite time ruin problems, some care has to be taken as to when the simulation should stop. An alternative is to simulate under an equivalent measure $\tilde{P}$ so that $\tilde{P}(T < \infty | Y_0 = y) = 1$. Then with M_t equal to $\frac{d\tilde{P}}{dP}$ restricted to $\sigma\{Y_s : s \leq t\}$,

$$\psi(y) = \tilde{E}[M_T^{-1} | Y_0 = y] \quad (13)$$

Hence what is required is repetitive simulation of M_T under $\tilde{P}$. The catch is that this kind of importance sampling is very dangerous (due to the possible explosion of the variance of the Monte Carlo estimator) and can lead to completely wrong results.

Asymptotic Results

If there are only a few papers dealing with numerical solutions, there is certainly a fair number dealing with asymptotic results, that is, the behavior of $\psi(y)$ or $\psi(t, y)$ when y gets large. To present a few of the most prominent or recent results, we shall need some definitions. As before, let $\bar{F}(x) = 1 - F(x)$ and let $F^{*n}(x)$ be the n -fold convolution of F .

- $F \in \mathcal{R}_{-\alpha}$ if $\bar{F}(x) = x^{-\alpha}l(x)$ where l is a slowly varying function, that is, $\lim_{x \rightarrow \infty} \frac{l(tx)}{l(x)} = 1$ for all $t > 0$.
- $F \in \mathcal{S}$ if $\lim_{x \rightarrow \infty} \frac{\bar{F}^{*2}(x)}{\bar{F}(x)} = 2$.

We have $\mathcal{R}_{-\alpha} \subset \mathcal{S}$. The class $\mathcal{S}$ is called the *class of subexponential distributions*, and among others it contains the lognormal, loggamma as well as the Weibull distribution with $\bar{F}(x) = e^{-(x/\beta)^\gamma}$ for $\gamma < 1$. It can be shown that if $F \in \mathcal{S}$, then $E[e^{tS}] = \infty$ for all $t > 0$, and hence the name *subexponential distribution*.

Culminating through a series of papers, it was proved in [12] that when $\sigma_R = 0$ and $F \in \mathcal{S}$,

$$\psi(t, y) \sim \frac{\lambda}{r} \int_y^{ye^{rt}} \frac{\bar{F}(x)}{x} dx, \quad 0 < t \leq \infty \quad (14)$$

For the light-tailed case with $\sigma_R = 0$, results are a little less explicit. Let $\kappa = \sup\{a : E[e^{aS}] < \infty\}$. Then it was proved in [7] that for any $\varepsilon > 0$,

$$\begin{aligned} \lim_{y \rightarrow \infty} y^{(\kappa-\varepsilon)y} \psi(y) &= 0 \quad \text{and} \\ \lim_{y \rightarrow \infty} y^{(\kappa+\varepsilon)y} \psi(y) &= \infty \end{aligned} \quad (15)$$

It was also shown by examples that anything can happen to $\lim_{y \rightarrow \infty} y^\kappa \psi(y)$.

When $\sigma_R > 0$ the picture is slightly less complex. The reason for this is that the financial risk caused by variations in the return process R corresponds to claims $F \in \mathcal{R}_{-\kappa}$ with $\kappa = \frac{2\kappa}{\sigma_R^2} - 1$. Hence, when claims have lighter tails than this, the asymptotics is dominated by R . Various results in this direction appear in the literature and the most precise results for the model studied here are those in [10]. There it is assumed that $\sigma_P = 0$, but due to the light-tailed effect of W_P , the result is valid for $\sigma_P > 0$ as well. To present the results, remember that $\psi(y) = 1$ when $\kappa \leq 0$, so assume that $\kappa > 0$ and also that $E[S] < \infty$.

1. If for some $\varepsilon > 0$, $E[S^{\kappa+\varepsilon}] < \infty$, then $\lim_{y \rightarrow \infty} y^\kappa \psi(y) = c$ for some (for all practical purposes) unknown c .
2. If $\bar{F}(x) = x^{-\rho}l(x)$ where $\rho < \kappa$, then

$$\psi(y) \sim \frac{2\lambda}{\sigma_R^2 \rho (\kappa - \rho)} y^{-\rho} l(y) \quad (16)$$

The limiting case $F \in \mathcal{R}_{-\kappa}$ needs to be treated separately [10].

Inequalities

Several inequalities for the ruin probability exist, but the problem is that either they are not very sharp or they are difficult to compute. An example that follows directly from equation (3) is

$$H(-y) \leq \psi(y) \leq \frac{H(-y)}{H(0)} \quad (17)$$

and when F has decreasing failure rate, the right-hand side can be strengthened to $\frac{H(-y)}{E[H(S)]}$. The problem here is that the distribution function H is not known.

An upper bound that is easier to compute, but restricted to the case with $\sigma_P = \sigma_R = 0$ and light-tailed claims, is given in [2]. To explain, assume that the equation

$$\lambda \left(\int_0^\infty e^{\gamma(s)x} dF(x) - 1 \right) - \gamma(s)(p + rs) = 0 \quad (18)$$

has a positive solution $\gamma^*(s)$ for all $0 \leq s \leq y$. Then

$$\psi(y) \leq e^{-\int_0^y \gamma^*(s) ds} \quad (19)$$

Phase-type Distribution

A phase-type distribution is a probability distribution that results from a system of one or more interrelated Poisson processes occurring in sequence or phases. Such distributions represent one of the most general classes of distributions permitting a probabilistic (i.e., Markovian) interpretation, as they are essentially based on the method of exponential stages technique that was introduced by Erlang in the early twentieth century and later generalized by Neuts in the mid-to-late 1970s. Phase-type distributions also possess a variety of desirable analytical properties that often facilitate their use in terms of yielding exact, algorithmically tractable, solution procedures. Phase-type distributions have been used extensively in many areas of applied probability, particularly in queueing theory (e.g., see [3]), actuarial risk theory (e.g., see [9]), and finance (e.g., see [4]). In addition, thorough treatments of phase-type distributions and their applications can be found in several reference texts including [1, 5, 7, 8, 10]. In what follows, we present only a brief overview of phase-type distributions and some of their key distributional properties.

In essence, phase-type distributions consist of a “general” mixture of exponentials and are characterized by an absorbing finite-state Markov chain. Specifically, let $\{X(t), t \geq 0\}$ represent a homogeneous, continuous-time Markov chain with transient states $\{1, 2, \dots, n\}$ and single absorbing state labeled $n + 1$. Define the row vector $\underline{\alpha} = (\alpha_1, \alpha_2, \dots, \alpha_n)$, wherein α_j represents the probability of beginning (at time 0) in a transient state j , $j = 1, 2, \dots, n$. The infinitesimal generator Q associated with this Markov process can be represented as

$$Q = \begin{bmatrix} S & \underline{s}_0 \\ \underline{0} & 0 \end{bmatrix} \quad (1)$$

In equation (1), S is an $n \times n$ nonsingular matrix containing the transition rates among the n transient states. The diagonal entries of S are necessarily negative, while the remaining entries of S are non-negative. Furthermore, $\underline{s}_0$ is the $n \times 1$ column vector of absorption rates into state $n + 1$ from the individual transient states. Necessarily, $\underline{s}_0 = -S\underline{e}$, where $\underline{e}$ denotes an $n \times 1$ column vector of ones. In addition, $\underline{0}$ represents a $1 \times n$ row vector of zeros.

Let Y represent the time to absorption into state $n + 1$, namely $Y = \inf\{t \geq 0 \mid X(t) = n + 1\}$. The random variable Y is said to have a continuous phase-type distribution with (parametric) representation $(\underline{\alpha}, S)$ of dimension n , often denoted as $Y \sim PH_n(\underline{\alpha}, S)$. The cumulative distribution function and density function of Y are given by

$$\begin{aligned} F(y) &= 1 - \underline{\alpha} \exp(Sy) \underline{e} \quad \text{and} \\ f(y) &= \underline{\alpha} \exp(Sy) \underline{s}_0 \quad \text{for } y \geq 0 \end{aligned} \quad (2)$$

where the matrix exponential in equation (2) is defined by $\exp(Sy) = \sum_{m=0}^{\infty} y^m S^m / m!$. Moreover, Y has Laplace–Stieltjes transform and integer moments given by

$$\begin{aligned} E\{e^{-tY}\} &= 1 - \underline{\alpha} \underline{e} + \underline{\alpha}(tI - S)^{-1} \underline{s}_0 \quad \text{and} \\ E\{Y^k\} &= (-1)^k k! \underline{\alpha} S^{-k} \underline{e} \end{aligned} \quad (3)$$

where I denotes an $n \times n$ identity matrix. Computation of the above matrix-based quantities is a routine task with the aid of most mathematical software packages in use today. A good reference for the calculation of matrix exponentials is [6].

One of the most important and useful features of the phase-type family of distributions is that the phase-type distribution is dense in the set of all positive-valued distributions, implying that it is (theoretically) possible to represent any positive-valued distribution with a “suitable” phase-type approximation. However, we emphasize the fact that the phase-type distribution is a light-tailed distribution (including combinations/mixtures of exponential and Erlang distributions as special cases), and thus it cannot be expected to fit a heavy-tailed distribution in the extreme tail. For an excellent treatment regarding phase-type fitting of arbitrary distributions, see [2] and references therein.

Numerous operations on phase-type distributions lead again to distributions that are phase-type with readily calculable parameters. This is a very appealing quality of phase-type distributions. In particular, convolutions, finite mixtures, and geometric compounds of phase-type distributions are again phase-type distributed. See [1, 7] for proofs of these results and further closure properties.

In conclusion, we state that a discrete analog to the continuous phase-type distribution exists by

considering the time to absorption in an equivalent discrete-time Markov chain. We direct interested readers to [5, 7] for further details on discrete phase-type distributions.

Credibility Theory

Credibility originates from the insurance industry and its basic idea goes back as far as the year 1918, when Whitney [20] was confronted with the problem of estimating risk premiums in workmen compensation. For the premium of an individual contract i , he suggested taking a weighted mean

$$\hat{\mu}_i = \alpha \bar{X}_i + (1 - \alpha) \bar{X} \quad (1)$$

where $\bar{X}_i$ is the observed average claim amount per volume unit for the individual contract i and $\bar{X}$ is the corresponding overall mean of the insurance portfolio. The expression *credibility* was originally used for the weight α in equation (1), which is a measure of reliability attached to the individual claims experience.

Since then, *credibility theory* has become an established discipline of insurance mathematics. Though mainly encountered in insurance applications, it also has the potential to be a powerful tool in the wider field of finance, where applications are found in credit risk (see **Credit Risk**) and in operational risk (see **Operational Risk**) assessments.

Credibility theory deals with the fundamental concepts of *individual risk* and *collective* or *individual claims experience* and *a priori knowledge*. The aim is to assess the individual risks. There are two sources of information on an individual risk: observations of the individual risk on the one hand, and *a priori* knowledge, gained from other similar risks in the portfolio (the collective) or from an expert opinion (personal belief), on the other.

Credibility theory can be described as follows:

- It answers the question of how one should combine the information out of the two sources to get a “best” estimate of the individual risk.
- It is the mathematical tool to describe heterogeneous collectives.
- It belongs mathematically to the area of Bayesian statistics.

A concise description of credibility theory and its development seen from the perspective of its essential mathematical structure can be found in [17]. References [5, 8] are some recent textbooks on credibility.

Credibility Estimators

In a simple set-up, the underlying paradigm is the “two-urn” model. The individual risk is characterized by its risk characteristic ϑ , which is drawn from the first urn describing the risk structure within the collective. Hence ϑ is a realization of a random variable Θ . Given $\Theta = \vartheta$, the claims are drawn from the second urn with distribution F_ϑ . The risk premium becomes a random variable $\mu(\Theta)$, which has to be estimated from the observed data $\mathbf{X}$. The objective is to find an estimator $\widehat{\mu(\Theta)}$, which minimizes the quadratic loss or mean squared error (mse)

$$\text{mse}(\widehat{\mu(\Theta)}) = E[(\widehat{\mu(\Theta)} - \mu(\Theta))^2] \quad (2)$$

The “two-urn” model formulates the problem in the language of Bayesian statistics. Essentially, this had already been done in the 1940s by Bailey [1], but it became well known only in the late 1960s, when it was set out clearly by Bühlmann in [2, 3].

The estimator minimizing equation (2) is the Bayes estimator

$$\mu(\Theta)^{\text{Bayes}} = E[\mu(\Theta) | \mathbf{X}] \quad (3)$$

In many models, it is a linear function of the observations. This is, in particular, the case for the one-parametric exponential family with its natural conjugate prior [13]. A famous example is the Poisson–Gamma model, where Θ is Gamma distributed and where the observations, the claim numbers, are Poisson distributed with parameter Θ . This model was the actuarial basis for the construction of bonus–malus systems in third-party motor liability. The case where the Bayes estimator is a linear function of the observations is referred to as *exact credibility*. As an example, we consider the situation where we want to design a bonus–malus scheme for fleets of cars. We assume that the *a priori* expected number of claims within a given period (e.g., 1 year) for a specific fleet i is equal to v_i , which is known and can be calculated on the basis of objective tariff variables. On the other hand, we know that things like driver education might have considerable influence and that the true expected number of claims for that particular fleet is $\mu(\Theta_i) = \Theta_i v_i$, where Θ_i is an unknown risk quality factor for that particular fleet with $E[\Theta_i] = 1$. We assume that we know from

portfolio experience of different fleets that the standard deviation of Θ_i is equal to τ . Now we have observed a number of N_i claims in the given period for fleet i . On the basis of the Poisson–Gamma model we then obtain the following bonus–malus factor by which the base premium is multiplied to obtain the experience-rated premium:

$$\widehat{\Theta}_i = 1 + \alpha_i \left(\frac{N_i}{v_i} - 1 \right), \text{ where } \alpha_i = \frac{v_i}{v_i + \tau^{-2}} \quad (4)$$

For instance, if $v_i = 20$, $N_i = 15$, and $\tau = 20\%$, then there results a bonus–malus factor of 89%.

In general, the Bayes estimator cannot be expressed in closed analytical form. Moreover, one has to specify the family $\{F_\vartheta\}$ of distributions as well as the structure distribution U , which are both mostly not known in practice.

The basic idea behind credibility is to *restrict* the class of allowable estimator functions to those which are *linear* in the components of the observation vector $\mathbf{X}$. *Credibility estimators* are therefore *linear Bayes estimators*, minimizing the mse within the class of linear estimators.

The so-called normal equations play a central role, that is, $\mu(\Theta)^{\text{cred}}$ is the credibility estimator of $\mu(\Theta)$ based on $\mathbf{X}^T = (X_1, \dots, X_n)$ if and only if it satisfies the normal equations

$$E[\mu(\Theta)^{\text{cred}} - \mu(\Theta)] = 0, \quad (5)$$

$$\begin{aligned} \text{Cov}[\mu(\Theta)^{\text{cred}}, X_j] &= \text{Cov}[\mu(\Theta), X_j] \\ \text{for } j &= 1, 2, \dots, n \end{aligned} \quad (6)$$

Hence the credibility estimator only depends on first and second moments and not on the whole underlying distributions.

The only mathematical structure in the most general credibility set-up is the fact that one wants to estimate a random variable $\mu(\Theta)$ based on a random vector $\mathbf{X}^T$. Neither $\mu(\Theta)$ nor the components of $\mathbf{X}^T$ are further specified, that is, the observations X_j can also be functions of some other original observations.

Credibility is most elegantly understood by looking at the space $\mathcal{L}^2$ of square integrable random variables. $\mathcal{L}^2$ together with the inner product $\langle X, Y \rangle := E[XY]$ is a Hilbert space. The corresponding norm of an X in $\mathcal{L}^2$ is $\|X\| = \sqrt{\langle X, X \rangle}$.

The advantage of looking at credibility in this way is that we can apply our intuitive understanding of the properties of linear vector spaces to the credibility problem. The mse of an estimator $\widehat{\mu}(\Theta)$ becomes $\|\widehat{\mu}(\Theta) - \mu(\Theta)\|^2$ and the credibility estimator is the point in the subspace $L(\mathbf{X}, 1) := \{\widehat{\mu}(\Theta) : \widehat{\mu}(\Theta) = a_0 + \sum_{j=1}^n a_j X_j, \quad a_0, a_1, \dots \in \mathbb{R}\}$ closest to $\mu(\Theta)$. Hence $\mu(\Theta)^{\text{cred}}$ is the orthogonal projection of $\mu(\Theta)$ on $L(\mathbf{X}, 1)$, and the normal equations (5) and (6) follow from the orthogonality property. For a historical perspective of the Hilbert space approach in the context of credibility, we refer to [9].

The Bühlmann–Straub Model

The Bühlmann–Straub (BS) [7] model is the best known credibility model that is widely used in practice. It extends the simple Bühlmann model [2] by allowing for observations with associated weights, which are very often encountered in practice such as when considering claim averages, claim frequencies, loss ratios, and so on.

The risks are embedded in a collective of similar risks numbered $i = 1, 2, \dots, I$, each of which is characterized by its own Θ_i and has observations $\{X_{ij} : j = 1, 2, \dots, n_i\}$ with associated weights w_{ij} . The BS model assumes that, conditionally on Θ_i , the random variables $\{X_{ij} : j = 1, 2, \dots, n_i\}$ are independent with

$$E[X_{ij} | \Theta_i] = \mu(\Theta_i) \quad (7)$$

$$\text{Var}[X_{ij} | \Theta_i] = \frac{\sigma^2(\Theta_i)}{w_{ij}} \quad (8)$$

that the pairs $(\Theta_1, \mathbf{X}_1), (\Theta_2, \mathbf{X}_2), \dots$ are independent and that $\Theta_1, \Theta_2, \dots$ are independent and identically distributed (i.i.d.).

A heterogeneous portfolio is modeled in this manner. The risks in the portfolio are different: they have different risk profiles Θ_i . But the risks in the portfolio also have something in common: *a priori*, they cannot be recognized as being different, which results from the fact that the risk profiles Θ_i are i.i.d.

The credibility estimator turns out to be a weighted mean

$$\mu(\Theta_i)^{\text{cred}} = \alpha_i \bar{X}_i + (1 - \alpha_i) \mu \quad (9)$$

where

$$\bar{X}_i = \sum_j \frac{w_{ij}}{w_{i\bullet}} X_{ij}, \quad w_{i\bullet} = \sum_j w_{ij}, \quad \alpha_i = \frac{w_{i\bullet}}{w_{i\bullet} + \frac{\sigma^2}{\tau^2}} \quad (10)$$

and where μ , σ^2 , and τ^2 are the so-called structural parameters

$$\mu = E[\mu(\Theta_i)], \quad \sigma^2 = E[\sigma^2(\Theta_i)], \quad \tau^2 = \text{Var}[\mu(\Theta_i)] \quad (11)$$

The mse is

$$\text{mse}(\mu(\Theta_i)^{\text{cred}}) = (1 - \alpha_i) \tau^2 = \alpha_i \frac{\sigma^2}{w_{i\bullet}} \quad (12)$$

The credibility estimator (9) has a natural interpretation. The expected value μ over the whole collective is the best estimator based only on the *a priori* knowledge and ignoring the individual observations, whereas $\bar{X}_i$ is the best linear estimator when looking only at the individual observations and ignoring the *a priori* knowledge (optimally compressed data, linear sufficient statistics). The credibility estimator takes both sources of information into account and is a weighted mean of the two components with weights inversely proportional to the mse. This *general intuitive principle* is also valid in the more general models.

The assumption that the risks in the portfolio are *a priori* equal is rather strong and often not fulfilled in practice. Often, there are known *a priori* differences between risks, that is, instead of equation (7) we have $E[X_{ij} | \Theta_i] = a_i \mu(\Theta_i)$ with known constants a_i . However, by a linear transformation one can transform the problem to the BS model and still apply it.

The credibility estimator (9) does not depend on the observations of the other risks in the portfolio. However, the structural parameters are usually not known, in practice, and have to be estimated from the data of the collective. For the overall mean μ , one can restrict the class of estimators further by allowing only linear estimators without a constant term. The best estimator out of this class is named the *homogeneous credibility estimator*, $\mu(\Theta_i)_{\text{hom}}^{\text{cred}}$, and contains a built-in estimator for μ . In the BS model it is obtained by replacing μ in equation (9) by

$$\hat{\mu} = \sum_i \frac{\alpha_i}{\alpha_{\bullet}} \bar{X}_i, \quad \text{where } \alpha_{\bullet} = \sum_i \alpha_i \quad (13)$$

When replacing the structural parameters in equation (9) by their estimated values, one arrives at the *empirical credibility estimator*. It can be shown [16] that under rather general conditions, the empirical credibility estimator converges in probability to the credibility estimator if the size of collateral data increases.

Hierarchical Credibility

Hierarchical credibility is an extension of the BS model in the sense that it generalizes the “two-urn” model to a “many-urn model”. In such models, the risk characteristics of the individual risks are drawn from a collective urn whose risk characteristics are drawn from a further parent urn and so on. Such hierarchies appear naturally in many situations. For instance, in insurance pricing, one often encounters the situation that individual risks are classified according to their “tariff positions”, tariff positions are grouped together into “subgroups”, subgroups into “groups”, groups into “main groups”, which together make the total of a line of business. A hierarchical model has the advantage of leading to a well-founded, properly balanced distribution of the burden of claims, in particular, of large claims, among the individual risks.

The concept of hierarchical credibility was introduced by Jewell [14] and Taylor [19]. It is best understood when looking at credibility estimators as orthogonal projections on linear subspaces, which, as shown in [6], leads to a recursive calculation of the credibility estimators. First, a linear sufficient statistics is calculated bottom up, and then the credibility estimators are calculated top down, where the estimators on the different levels have the same structure as the ones in the BS model.

Multidimensional Credibility

The essence of *multidimensional credibility* is that one wants to estimate a real-valued vector $\boldsymbol{\mu}(\Theta) = (\mu_1(\Theta), \dots, \mu_p(\Theta))^T$ as, for instance, the claims load for “normal claims” and “big claims”, “claim frequency” and “claim size”, the claims load in different layers, and so on. The point is that one estimates the components of $\boldsymbol{\mu}(\Theta)$ *simultaneously* on the basis of the same observation vector $\mathbf{X}$. For instance, when estimating the claims load for big

claims, one also looks at the observed claims load for normal claims, and *vice versa*.

Multidimensional credibility was introduced by Jewell [12]. A convenient way is to consider an abstract setup, where $\mathbf{X}$ has the same dimension as $\boldsymbol{\mu}(\Theta)$ with $E[\mathbf{X}|\Theta] = \boldsymbol{\mu}(\Theta)$ and $\text{Cov}(\mathbf{X}, \mathbf{X}^T|\Theta) = \Sigma(\Theta)$. This vector $\mathbf{X}$ may be obtained by data compression from the raw data. The structure of the credibility estimator inherits its form from the simple model and becomes

$$\boldsymbol{\mu}(\Theta)^{\text{cred}} = A\mathbf{X} + (I - A)\boldsymbol{\mu} \quad (14)$$

where

$$A = T(T + S)^{-1} \quad (15)$$

is the credibility matrix, I is the identity matrix, and

$$\begin{aligned} \boldsymbol{\mu} &= E[\boldsymbol{\mu}(\Theta)], \quad S = E[\Sigma(\Theta)], \\ T &= \text{Cov}[\boldsymbol{\mu}(\Theta), \boldsymbol{\mu}(\Theta)^T] \end{aligned} \quad (16)$$

are the structural parameters.

Mostly, one is not primarily interested in the individual components of the vector $\boldsymbol{\mu}(\Theta)$, but rather in a linear combination

$$\mu(\Theta) := \sum_{k=1}^p a_k \mu_k(\Theta) = \mathbf{a}^T \boldsymbol{\mu}(\Theta) \quad (17)$$

For the mse of $\mu(\Theta)$ one obtains

$$\text{mse}(\mu(\Theta)) = \mathbf{a}^T V_2 \mathbf{a} \quad (18)$$

where

$$V_2 = (I - A)T = AS \quad (19)$$

is the *mse matrix*.

The optimal data compression to reduce the raw data to a vector $\mathbf{X}$ of the same dimension as $\boldsymbol{\mu}(\Theta)$ is discussed in [5] and can be expressed as an orthogonal projection on a translated subspace

$$\mathbf{B} = \text{Pro}(\boldsymbol{\mu}(\Theta) | L_e^{\text{ind}}(\mathbf{X})) \quad (20)$$

where

$$\begin{aligned} L_e^{\text{ind}}(\mathbf{X}) &= \left\{ \widehat{\boldsymbol{\mu}(\Theta)} : \widehat{\mu_k(\Theta)} = \sum_j a_j^{(k)} X_j \right. \\ &\quad \left. \text{for } k = 1, \dots, p; E[\widehat{\boldsymbol{\mu}(\Theta)} | \Theta] = \boldsymbol{\mu}(\Theta) \right\} \end{aligned} \quad (21)$$

Credibility in the Regression Case

The credibility regression model was introduced by Hachemeister [11] and motivated by the problem of forecasting average claim amounts for bodily injury claims in third-party auto liability for various states in the United States. In contrast to classical statistics, the regression parameters are assumed to be a random vector $\boldsymbol{\beta}(\Theta)$, that is, it is assumed that

$$E[\mathbf{X}|\Theta] = Y\boldsymbol{\beta}(\Theta) \quad (22)$$

$$\text{Cov}(\mathbf{X}, \mathbf{X}^T|\Theta) = \Sigma(\Theta) \quad (23)$$

where $\mathbf{X}$ is the observation vector of a particular risk, Y is the corresponding design matrix and $\boldsymbol{\beta}(\Theta)$ the regression vector. The credibility estimator of $\boldsymbol{\beta}(\Theta)$ is most elegantly found by making use of the multidimensional credibility result. The optimal data compression is

$$\mathbf{B} = (Y^T S^{-1} Y)^{-1} Y^T S^{-1} \mathbf{X} \quad (24)$$

and by applying equation (14) one obtains

$$\boldsymbol{\beta}(\Theta)^{\text{cred}} = A\mathbf{B} + (I - A)\boldsymbol{\beta} \quad (25)$$

where

$$\begin{aligned} A &= T \left(T + (Y^T S^{-1} Y)^{-1} \right)^{-1} \\ \boldsymbol{\beta} &= E[\boldsymbol{\beta}(\Theta)], \quad S = E[\Sigma(\Theta)], \\ T &= \text{Cov}[\boldsymbol{\beta}(\Theta), \boldsymbol{\beta}(\Theta)^T] \end{aligned} \quad (26)$$

In many practical situations,

$$\Sigma(\Theta) = \sigma^2(\Theta)W^{-1} \quad (27)$$

where W is a diagonal matrix with known weights w_j down the diagonal. Then

$$\mathbf{B} = (Y^T W Y)^{-1} Y^T W \mathbf{X} \quad (28)$$

$$A = T \left(T + \sigma^2 (Y^T W Y)^{-1} \right)^{-1},$$

$$\text{where } \sigma^2 = E[\sigma^2(\Theta)] \quad (29)$$

When Hachemeister applied the theory to his data on bodily injury (a case of simple regression), he

obtained some “rather strange” results for some of the states. The solution is found in [4]: one should work with an orthogonal design matrix. In the simple linear regression case, this means that one should choose the barycenter not at the origin but rather at the center of gravity of time. Then the credibility estimators for the two regression components “barycenter” and “slope” split into two one-dimensional credibility formulas of the same type as in the BS-model.

Evolutionary Credibility Models

Evolutionary credibility models are characterized by the fact that the risk parameters vary stochastically in time. Such models are closely tied to recursive credibility formulae often referred to as *recursive credibility*.

References [10, 18] are some of the early actuarial papers devoted to *evolutionary or recursive credibility*. A well-known recursive procedure developed in an engineering context is the Kalman Filter [15] (see also **Filtering**).

In the *one-dimensional evolutionary credibility model*, a specific risk with observation vector $\mathbf{X}$ is again characterized by its individual risk profile. However, this risk profile is itself a stochastic process, that is, a sequence of random variables

$$\Theta = \{\Theta_1, \Theta_2, \dots, \Theta_j, \dots\} \quad (30)$$

The components Θ_j are to be understood as the risk profile in year j and it is assumed that

$$E[X_j | \Theta] = E[X_j | \Theta_j] = \mu(\Theta_j) \quad (31)$$

$$\text{Var}[X_j | \Theta] = \text{Var}[X_j | \Theta_j] = \frac{\sigma^2(\Theta_j)}{w_j} \quad (32)$$

where X_j is the observation in year j , w_j an appropriate weight and $E[\sigma^2(\Theta_j)] = \sigma^2$. The aim is to find for each year n the credibility estimator of $\mu(\Theta_n)$ based on the observations $\{X_1, \dots, X_{n-1}\}$.

It is useful to split up the step from $\mu(\Theta_n)^{\text{cred}}$ to $\mu(\Theta_{n+1})^{\text{cred}}$ into two steps:

1. Updating

Improve the estimation of $\mu(\Theta_n)$ on the basis of the newest information X_n .

2. Parameter movement

Change the estimation owing to the switch of the parameter from $\mu(\Theta_n)$ to $\mu(\Theta_{n+1})$.

In this connection, it is suitable to introduce the terminology and notation from state space models:

$$\begin{aligned} \mu_{n|n-1} &:= \text{Pro}(\mu(\Theta_n) | L(1, X_1, \dots, X_{n-1})), \\ \mu_{n|n} &:= \text{Pro}(\mu(\Theta_n) | L(1, X_1, \dots, X_{n-1}, X_n)), \\ q_{n|n} &:= E[(\mu_{n|n} - \mu(\Theta_n))^2], \\ q_{n|n-1} &:= E[(\mu_{n|n-1} - \mu(\Theta_n))^2] \end{aligned} \quad (33)$$

Here $\mu_{n|n-1}$ is just another notation for $\mu(\Theta_n)^{\text{cred}}$, which is the credibility estimator of $\mu(\Theta_n)$ based on the observations $X_1, \dots, X_{n-1}$, whereas $\mu_{n|n}$ is the updated estimator of $\mu(\Theta_n)$ based on the observations $X_1, \dots, X_{n-1}, X_n$.

If the observations in different years are, on the average, conditionally uncorrelated, and if the process $\mu(\Theta)$ has orthogonal increments, that is, if

$$E[\text{Cov}(X_k, X_j | \Theta)] = 0 \quad (34)$$

$$\begin{aligned} \text{Pro}(\mu(\Theta_{n+1}) | L(1, \mu(\Theta_1), \dots, \mu(\Theta_n))) \\ = \mu(\Theta_n) \quad \text{for } n \geq 1 \end{aligned} \quad (35)$$

then the credibility estimators can be calculated by the following recursive procedure (“Kalman filter notation”):

1. Anchoring (Period 1)

$$\begin{aligned} \mu_{1|0} &= E[\mu(\Theta_1)] \quad \text{and} \\ q_{1|0} &= E[(\mu_{1|0} - \mu(\Theta_1))^2] \end{aligned} \quad (36)$$

2. Recursion ($n \geq 1$)

(a) Updating

$$\mu_{n|n} = \alpha_n X_n + (1 - \alpha_n) \mu_{n|n-1} \quad (37)$$

$$\text{where } \alpha_n = \frac{q_{n|n-1}}{q_{n|n-1} + \frac{\sigma^2}{w_n}},$$

$$q_{n|n} = (1 - \alpha_n) q_{n|n-1} \quad (38)$$

(b) Change from $\mu(\Theta_n)$ to $\mu(\Theta_{n+1})$ (parameter movement)

$$\mu_{n+1|n} = \mu_{n|n} \quad (39)$$

$$q_{n+1|n} = q_{n|n} + \delta_{n+1}^2 \quad (40)$$

where $\delta_{n+1}^2 = \text{Var}[\mu(\Theta_{n+1}) - \mu(\Theta_n)]$.

The collection of models can be enlarged by allowing linear transformation on the right-hand side of equation (35) and adjusting equations (39) and (40) accordingly.

The evolutionary model sketched here can easily be extended to the *evolutionary regression credibility model*. By an appropriate choice of the components of $\beta(\Theta_n)$, the evolutionary regression model allows the modeling of a large number of evolutionary phenomena. In particular, one can model in this way all situations where the process $\{\mu(\Theta_j) : j = 1, 2, \dots\}$ is an autoregressive moving average (ARMA) process (see **Autoregressive Moving Average (ARMA) Processes**). Analogously, one can extend the idea to the multidimensional case and consider the *evolutionary multidimensional credibility model*. It allows to model situations where the individual risk over time depends both on specific individual factors as well as on global factors affecting all risks in the collective simultaneously (see [5] for further details). Such models might, besides insurance, also be suitable for applications in finance.

Life Insurance

Finance and life insurance have a lot in common. Life insurance contracts specify an exchange of streams of payments between the insurance company and the contract holder. These payment streams may cover the lifetime of the contract holder. Therefore, time valuation of money is crucial for any measurement of payments due in the past as well as in the future. Life insurance companies never keep their money idle, and accumulation and distribution of capital gains are always a part of the insurance business. With respect to the future, appropriate discounting of contractual obligations improves the estimates of liabilities.

The subject matter of life insurance draws on a wide set of mathematical disciplines including probability theory, stochastic processes, statistics, economics, and mathematical finance. However, in addition, less positivistic areas such as accounting and law, in general, and insurance accounting, contractual law, and regulatory law, in particular, often play important roles when theory meets practice. The broad title covers a survey of the mathematics of life insurance rather than life insurance in general.

At the end of the day, life insurance is a betting game on life history events such as death, survival, and disability. Betting in this context is very different from betting on horses or football since the benefit is paid conditional on a life history event that has already caused financial distress of the betting party: one buys a coverage against death to protect one's dependants—typically spouse and children—financially against the loss of future income upon death; one buys life annuities to protect oneself financially against living long by stretching out capital holdings until an uncertain time of death; and one buys a coverage against disability to protect oneself and one's dependants financially against the loss of income upon disability. In this respect, insurance and pension saving are betting games that hedge the personal financial position against financially adverse events. However, this explains why the society encourages its members to play this betting game (partly in contrast to other betting games) under slightly regulated conditions: it has a stabilizing effect on the financial position of individuals and families and thereby on the society as a whole.

The insurance companies and pension funds are the counterparts of this betting game. This exposition

deals, first of all, with the technical toolbox they use in order to provide relevant, fair, and reliable bets. However, it also deals with the enlargement of the toolbox caused by the integration of mathematical finance as a part of life insurance mathematics. New paradigms lead to new answers to what the terms relevant, fair, and reliable mean at all. However, the enlightenment is not one way: some of the classical tools of life insurance are relevant to modern finance and we provide an example.

The section Modeling of Payment Streams presents the classical modeling framework for life history risk and the payment streams linked to it, first in the so-called survival model and second in a multistate model. The section Valuation of Payment Streams deals with the valuation of and fairness criteria for these payment streams. First, we evaluate on the basis of classical actuarial assumptions and then discuss how the financial market helps to relax some of these assumptions. Finally, we exemplify by credit risk modeling and valuation, how methods of classical life insurance can also contribute to a structured view on modern financial topics. The section Design of Payment Streams formalizes the so-called participation feature in typical practical arrangements that add a dimension to the risk sharing taking place in an insurance contract. We distinguish between the classical with-profit construction, where design and decision is primarily a matter for the insurance company, and the more modern unit-link, where design and decision, to a larger extent, is a matter for the policy holder. Finally, in the section Management of Payment Streams, we focus on these decision processes. Optimal decision making on both sides of the balance scheme is the essence of asset-liability management (ALM). We conclude by relating these decision processes to those in the classical investment–consumption problem of personal finance.

Modeling of Payment Streams

The Survival Model Payment Streams

The payments of an insurance contract can be formalized by a payment process B , where $B(t)$ represents the accumulated payments from the insurance company to the policy holder until time t . The payments are then the increments $(dB(t))_{t \geq 0}$ and we have that

$$B(t) = \int_{0-}^t dB(s) \quad (1)$$

where, by definition, $\int_0^t = \int_{(0,t]}$ and $\int_{0-}^t = \int_{[0,t]}$. Thus, payments going from the insurance company to the policy holder (benefits) appear in B as positive increments, whereas payments going from the policy holder to the insurance company (premiums/contributions) appear in B as negative increments. In the formation of B , we have assumed that there are no payments before inception of the contract at time 0, that is, $B(0-) = 0$. We specify the payments in a continuous-time framework. We denote by T the time of death of a policy holder. To formalize the connection between payments and the life history of the insured, we introduce the indicator process $I(t)$. This process indicates whether the insured is alive in the sense that $I(t) = 1$ if the insured is alive at time t and $I(t) = 0$ if the insured is dead at time t . The process $Z(t) = 1 - I(t)$ indicates whether the insured is dead, which is illustrated in Figure 1.

We also introduce a counting process $(N(t))_{t \geq 0}$, counting the number of deaths of the insured (equals 0 or 1) over $[0, t]$. Note that $N = Z = 1 - I$. Finally, we introduce the notation $(\varepsilon^u(t))_{t \geq 0}$ for the deterministic indicator process, indicating that t exceeds u , that is, $\varepsilon^u(t) = 1 [t \geq u]$. Fixing a time horizon n for the insurance contract and introducing a retirement time $m \leq n$, most insurance payment processes in a survival model are given by a payment process B in the following form:

$$dB(t) = \Delta B^0(t)d\varepsilon^0(t) + b^0(t)I(t)dt + b^{01}(t) \times dN(t) + \Delta B^0(t)I(t)d\varepsilon^m(t), \quad t \leq n \quad (2)$$

Here, $\Delta B^0(0)$ is a possible single premium (negative) triggered at time 0, $b^0(t)$ is an annuity benefit rate (positive) or a level premium rate (negative) at time t , both conditional on survival by multiplication of I , $b^{01}(t)$ is a death benefit triggered upon death before time n , and $\Delta B^0(m)$ is a pension sum benefit triggered at time m upon survival to time m . In Table 1, we specify the elements in some standard forms of benefit and premium payment processes.

To have an idea about the future prospects of B , we need to specify the distribution of T . We form the

Figure 1 Survival model

survival function $\bar{F}$, the lifetime distribution function F , and the death density, respectively,

$$\begin{aligned} \bar{F}(t) &= P(T > t) = P(I(t) = 1) \\ F(t) &= P(T \leq t) = P(I(t) = 0) = 1 - \bar{F}(t) \\ f(t) &= \frac{d}{dt}F(t) \end{aligned} \quad (3)$$

The distribution of T is typically parameterized by the hazard rate conventionally denoted by μ (Greek m for mortality rate) and defined as the death rate conditional on survival,

$$\begin{aligned} \mu(t)dt &= P(t \leq T < t + dt | T > t) \\ &= \frac{f(t)dt}{\bar{F}(t)} = -\frac{\bar{F}'(t)dt}{\bar{F}(t)} \end{aligned} \quad (4)$$

This forms a differential equation for $\bar{F}$ with initial condition $\bar{F}(0) = 1$. Its solution $\bar{F}$ and the resulting F and f are given as

$$\begin{aligned} \bar{F}(t) &= e^{-\int_0^t \mu(s)ds}, \quad F(t) = 1 - e^{-\int_0^t \mu(s)ds}, \\ f(t) &= e^{-\int_0^t \mu(s)ds} \mu(t) \end{aligned} \quad (5)$$

thereby forming the elementary distribution characteristics in terms of the mortality rate. One of the advantages from representing these characteristics in terms of the mortality rate is that the corresponding quantities conditional on survival until a given age, say x , have the same structure with $\mu(t)$ replaced by $\mu(x+t)$, for example,

$$P(T > x + t | T > x) = e^{-\int_0^t \mu(x+s)ds} \quad (6)$$

This is useful when the insurance company sells a contract to an x -year old and takes into account the fact that he/she survived so far. There are many candidates for the mortality rate that can take any form as long as $\mu(t) \geq 0$ and it integrates to infinity over $[0, \infty)$. The Gompertz–Makeham mortality rate

$$\mu(t) = \alpha + \beta e^{\gamma t} \quad (7)$$

allows for a nonage-dependent effect α (death from accident) and an exponential age-dependent effect (death from deterioration of health over time). This is classic due to its good fit to data relative to its low number of parameters. In the Danish mortality law

Table 1 Elementary life insurances

	$\Delta B^0(0)$	$b^0(t)$	$b^{01}(t)$	$\Delta B^0(m)$
Benefits				
Pure endowment	0	0	0	1
Term insurance	0	0	$1[t \leq m]$	0
Endowment insurance	0	0	$1[t \leq m]$	1
Temporary life annuity	0	$1[t \leq n]$		
Deferred temporary life annuity	0	$1[m < t \leq n]$		
Premiums				
Single premium	-1			
Level premium		$-1[t \leq m]$		

G82 for Danish males, the parameters are $\alpha = 5 \times 10^{-4}$, $\beta = 7.5858 \times 10^{-5}$, and $\gamma = \log(1.09144)$.

The Multistate Model Payment Streams

Although the payment process in equation (2) formalizes a number of standard forms of benefits and premium payment processes, there is a number of contracts that are not covered. An example is a contract where the level premium is not paid during periods of disability, that is, the level premium is contingent on the state of health. Such so-called premium waiver conditions and different types of disability annuities can be covered by extending the survival model with a third state, “disabled” (Figure 2).

Another example is a widow’s/widower’s pension where the two spouses in a married couple are insured such that, for example, an annuity rate is payable in the time period where one spouse survives another. Insurances on two lives can be covered by combining two survival models (Figure 3). It is now easy to

imagine a combination of Figures 2 and 3 into a dependent lives model with disability.

In general, we let Z be a process moving around in a finite number of states numbered from 0 to J . For such a process, we introduce two vectors of processes: the indicator process I^j , $j \in \{0, \dots, J\}$ indicates sojourn in state j and the counting process N^j , $j \in \{0, \dots, J\}$ counts the number of jumps into state j . Note that, in contrast to the survival model, the counting processes are in general not necessarily equal to 0 or 1: for example, in a disability model, the policy holder can move back and forth between “disabled” and “active”. Formally,

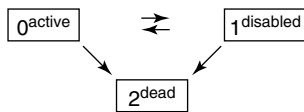

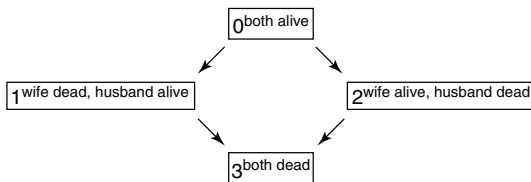

$$I^j(t) = 1[Z(t) = j]$$

$$N^j(t) = \#\{s \leq t : Z(s-) \neq j, Z(s) = j\} \quad (8)$$

We can now formalize a set of general payment processes driven by a multistate model (by convention, $Z(0) = 0$),

$$\begin{aligned} dB(t) = & \Delta B^0(t) d\epsilon^0(t) + \sum_j I^j(t) b^j(t) dt \\ & + \sum_k \sum_{j:j \neq k} I^j(t-) b^{jk}(t) dN^k(t) \\ & + \sum_j I^j(t) \Delta B^j(t) d\epsilon^m(t), t \leq n \quad (9) \end{aligned}$$

Here, $\Delta B^0(0)$ is a possible single premium (negative) triggered at time 0, $b^j(t)$ is a payment rate (positive or negative) at time t conditional on sojourn in state j , $\Delta B^j(t)$ is a lump sum payment at time t conditional on sojourn in state j , and $b^{jk}(t)$ is an insurance sum triggered and paid upon a transition from state j to state k . Note that, for example, in

**Figure 2** Disability model**Figure 3** Dependent lives model

the disability model, N^2 counts the number of deaths no matter from which state the death occurs; but by the specification of j in b^{j2} and multiplication by $I^j(t-)$ the death sum is allowed to depend on this information.

To have an idea about the future prospects of B , we need to specify the distribution of Z . The traditional approach is to assume the existence of deterministic piecewise continuous functions $\mu^{jk}(t)$ such that the distribution of N^k is characterized by its intensity $\mu^{Z(t-),k}(t)$. This means that the probability of experiencing a transition into state k over $[t, t + dt)$ is proportional to the time interval dt with proportionality factor $\mu^{Z(t-),k}(t)$. We allow this to depend on $Z(t-)$ such that, for example, in the disability model we can have a mortality intensity that depends on whether the policy holder is active or disabled. Given that these intensities exist, Z is a time-inhomogeneous multistate Markov process.

In more general models, one loosens up the Markov assumption (see **Markov Processes**) and works with, for example, semi-Markov models where the transition intensity into a given state does not only depend on where the policy holder is but also depends on how much time he/she has spent there. This is relevant in the disability model, where the mortality rate from the state “disabled” at a given age may depend on the duration of disability. Even if one sticks to a Markov model for Z , the duration of sojourn may still be needed as a state process to formalize, for example, the annuity payments depending on the duration. The main example is the so-called qualification period that has to be spent as disabled before the disability annuity starts. Note carefully the difference between taking duration as a part of the probability model and taking it as a part of the state process formalizing the payment process. In the following section, we give more examples of relaxation of the Markov property of Z .

Valuation of Payment Streams

Classical Valuation Based on Three Assumptions

We assume that the payments are currently deposited on (or withdrawn from) an account that bears interest at rate $r(t)$ at time t . We can now arrive at the present value at time t of a payment process by adding up the values of all elements in the payment process. We get the present value at time t of the payment process B :

$$\int_{0-}^n e^{-\int_t^s r(\tau) d\tau} dB(s) \quad (10)$$

The value at time 0 of a payment process B is the net loss at time 0 that the insurance company faces by initiation of the contract. If the processes describing the policy holder’s life history and the interest rate were known at time 0, this net loss could be calculated at time 0. To avoid losses (and gains), one should ideally balance the elements in the payment process such that the net loss is 0:

$$\int_{0-}^n e^{-\int_0^t r(s) ds} dB(t) = 0 \quad (11)$$

However, the processes for the policy holder’s life history and the interest rate are not known at time 0. We consider these processes as stochastic processes defined on a filtered (see **Filtrations**) probability space $(\Omega, \mathcal{F}, \{\mathcal{F}(t)\}_{t \geq 0}, P)$ such that the present value at time 0 becomes a stochastic variable and its outcome is revealed over time. The question is how one should balance the elements of the insurance contract in that situation.

A particular situation arises if we work under the following condition.

Condition 1

1. The insurance company issues (or can issue) contracts to a “large” number v of individuals with identically distributed payment processes $(B^i)_{i=1, \dots, v}$.
2. For all $i, j, i \neq j$, B^i is independent of B^j .
3. The interest rate is deterministic.

Then the law of large numbers applies and provides that the average gain from a contract converges toward the expected gain from a single contract (skipping the i then) as the number of contracts tends to infinity, that is,

$$\begin{aligned} & \frac{1}{v} \sum_{i=1}^v \int_{0-}^n e^{-\int_0^t r(s) ds} dB^i(t) \\ & \xrightarrow{P} E \left[\int_{0-}^n e^{-\int_0^t r(s) ds} dB(t) \right] \end{aligned} \quad (12)$$

To avoid *systematic* gains (and losses), one should, therefore, balance the elements in the payment

process such that the expected net gain is equal to 0,

$$E \left[\int_{0-}^n e^{-\int_0^t r(\tau) d\tau} dB(t) \right] = 0 \quad (13)$$

This balance equation formalizes the *principle of equivalence* that is fundamental in classical life insurance mathematics.

If one of the three assumptions fails, the classical principle of equivalence fails as a balancing tool for the elements in the payment process: if the insurance company cannot issue a large number of contracts, it makes no sense to draw conclusions from the law of large numbers; if B^i and B^j are dependent for $i \neq j$, the law of large numbers does not apply; and if the interest rate is not deterministic, we cannot deduce independence between present values from independence between payment processes. It should be mentioned, however, that Condition 1 can be weakened such that it holds only in a certain asymptotic sense.

Actually, the insurance company is interested in the valuation of the future payments not only at time 0 but also at any point in time t during the term of contract. This is required to inform the policy holder about the financial status of his/her contract and to inform the financial market and the regulators about the financial status of the insurance company. To estimate the present value of future payments at time t , $\int_t^n e^{-\int_t^s r(\tau) d\tau} dB(s)$, the insurance company naturally takes into account all information it possesses at that point in time. If we work under Condition 1 and in the multistate Markov model, we can argue, by the law of large numbers, for the valuation formula:

$$E \left[\int_t^n e^{-\int_t^s r(\tau) d\tau} dB(s) \middle| Z(t) \right] = \sum_j I^j(t) V^j(t) \quad (14)$$

where

$$V^j(t) = E \left[\int_t^n e^{-\int_t^s r(\tau) d\tau} dB(s) \middle| Z(t) = j \right] \quad (15)$$

These so-called statewise reserves are fundamental quantities in classical life insurance mathematics. They are characterized by a system of ordinary differential equations and presented in [6] as an inevitable tool for life insurance mathematicians. Substituting the payment process (9) into the reserve for state j , we get the differential equation (*see Markov Processes*):

$$\begin{aligned} \frac{d}{dt} V^j(t) &= r(t) V^j(t) - b^j(t) \\ &\quad - \sum_{k:k \neq j} \mu^{jk}(t) (b^{jk}(t) + V^k(t) - V^j(t)) \end{aligned} \quad (16)$$

which holds outside $\{0, m, n\}$. Inside $\{0, m, n\}$, the conditions are

$$\begin{aligned} V^j(n) &= 0 \\ V^j(m-) &= \Delta B^j(m) + V^j(m) \\ V^j(0-) &= \Delta B^j(0) + V^j(0) \end{aligned} \quad (17)$$

Note that, by taking the process Z to start in state 0 by convention, we can formulate the equivalence principle in terms of the statewise reserve:

$$V^0(0-) = \Delta B^0(0) + V^0(0) = 0 \quad (18)$$

The special case of the differential equation (16) that holds for the survival model was discovered by Thiele in 1875. In addition, generalized versions like, for example, equation (16) are spoken of as Thiele's differential equation. Interestingly, Thiele was actually also the first to model the Brownian motion mathematically in connection with his study of time series [5, 19]. Classical valuation formulas of classical life insurance products can be found in the textbook [4]. See also [13] for an account of different notions of reserves.

Example 1 Let us calculate the equivalence level premium for an endowment insurance sold to an x -year old based on the assumptions above. Plugging in the elementary endowment insurance benefits and a level premium rate π (Greek p for premium), the equivalence principle reads

$$\begin{aligned} &E \left[\int_{0-}^m e^{-\int_0^t r(s) ds} (-\pi I(t) dt + dN(t) \right. \\ &\quad \left. + I(t) d\mathcal{E}^m(t) \right) \Big] \\ &= E \left[\int_{0-}^m e^{-\int_0^t r(s) ds} (-\pi I(t) dt + dN(t) \right. \\ &\quad \left. + e^{-\int_0^m r(s) ds} I(m) \right) \Big] = 0 \end{aligned} \quad (19)$$

where expectation is actually conditional expectation given that the policy holder is x years old, that is, $T > x$. This forms one equation (the principle of equivalence) with one unknown (π) and its solution is called the equivalence premium. By plugging in the characteristics of the lifetime distribution in equation (5) and collecting terms, we get

$$\begin{aligned} & \int_{0-}^m e^{-\int_0^t (r(s) + \mu(x+s)) ds} (-\pi + \mu(x+t)) dt + e^{-\int_0^m (r(s) + \mu(x+s)) ds} = 0 \\ \Rightarrow & \frac{\int_{0-}^m e^{-\int_0^t (r(s) + \mu(x+s)) ds} \mu(x+t) dt + e^{-\int_0^m (r(s) + \mu(x+s)) ds}}{\int_{0-}^m e^{-\int_0^t (r(s) + \mu(x+s)) ds} dt} = \pi \end{aligned} \quad (20)$$

Actuaries have developed a shorthand notation for expected present values of standard payment streams. An actuary could write the premium formula above in code:

$$\pi = \frac{A_{x:m}}{a_{x:m}} = \frac{A_{x:m}^1 + {}_mE_x}{a_{x:m}} \quad (21)$$

The reserve to set up at time t given that the policy holder is alive is then given by

$$\begin{aligned} V^0(t) &= E \left[\int_t^m e^{-\int_t^s r(\tau) d\tau} (-\pi I(s) ds + dN(s)) \right. \\ &\quad \left. + e^{-\int_t^m r(s) ds} I(m) \middle| I(t) = 1 \right] \\ &= \int_t^m e^{-\int_t^s (r(\tau) + \mu(x+\tau)) d\tau} (-\pi + \mu(x+s)) ds \\ &\quad + e^{-\int_t^m (r(s) + \mu(x+s)) ds} \end{aligned} \quad (22)$$

It is easy to verify that this reserve actually fulfills the special case of the Thiele differential equation,

$$\frac{d}{dt} V^0(t) = r(t) V^0(t) + \pi - \mu(t) (1 - V^0(t)) \quad (23)$$

with the terminal condition given by definition,

$$V^0(m-) = 1 \quad (24)$$

and the initial condition as a result of inserting the equivalence premium calculated above,

$$V^0(0) = 0 \quad (25)$$

Can the Financial Market Relax the Three Assumptions?

In this subsection, we discuss how mathematical finance can help us relax parts of Condition 1 and the valuation principles and formulas that follow from such a relaxation.

The “Large Number” Assumption

This is inevitable for the law of large numbers to apply and we mention just, in passing, some of its counterparts in finance. In capital asset pricing model (CAPM; *see* **Capital Asset Pricing Model**) the hypothesis is that only systematic risk (aka systematic risk, market risk (*see* **Market Risk**), and nondiversifiable risk and is the risk that hits large numbers of assets in the market or the whole economy) has a price, in terms of expected return, while there is no price for taking unsystematic risk (aka idiosyncratic risk and diversifiable risk and is the risk that hits only one or a small number of assets in the market). The motivation is that unsystematic risk can be avoided without loss of expected return by choosing a sufficiently diversified portfolio. In arbitrage pricing theory (APT; *see* **Arbitrage Pricing Theory**), the CAPM is connected to arbitrage pricing by introducing the notion of asymptotic arbitrage. The conclusion is that to avoid asymptotic arbitrage (excess return for taking risk that can be cleared away

by diversification), the price of unsystematic risk cannot be systematically positive, but one cannot say much about the price of unsystematic risk in a particular asset.

In insurance terms, the explanation is as follows: to avoid systematic gains (and losses), the price for taking unsystematic risk must be zero, leading to the equivalence principle under the objective measure. An asymptotic arbitrage argument would give access to a positive price for taking on insurance risk from particular policy holders as long as this does not happen systematically across the policy holders in a large portfolio. However, competition among insurance companies and/or regulation will typically prevent that particular policy holders pay premiums that are larger than their expected benefits.

The Independence Assumption

This can be relaxed to some extent with some help from financial market considerations and actions. This is convenient since the independence assumption is difficult to justify in practice. The help from financial market considerations and actions depends on the source of dependence. Here, we distinguish between two different sources both coming from insufficiency in the model presented in the section Modeling of Payment Streams: first, in practice, the payment coefficients $b^j(t)$, $b^{jk}(t)$, and $\Delta B^j(t)$ are typically not only dependent on the policy holder state but also on the financial performance of some investment fund or index. Second, in practice, the Markov assumption is violated by uncertainties in demographic trends and movements coming from sociological, medicinal, and economic developments.

First, the payment coefficients are supposed to protect buying power upon insurance events rather than nominal values. Therefore, the contracts typically contain participation features in the sense that the policy holder participates in the capital gains of some investment fund. The participation is either directly spelled out in the contract (unit-linked life insurance) or indirectly enforced by the legislative environment in which the contract is underwritten (with-profit life insurance). Additionally, the payments may be linked to the policy holder's salary or some salary index. We take a closer look at these participation features in the section Design of Payment Streams.

Such participation features affect the valuation since they create dependence between payment processes. To the extent that the dependence is created

by financial market risk, a natural idea is to adopt other valuation techniques available for that part of the risk, for example, no arbitrage pricing. A example is to let the payment coefficients be contingent claims formalized as functions of an asset price. Consider, for example, the endowment insurance studied in Example 1, with the modification that a function f of the asset price at time m , $S(m)$, is paid out as benefit conditional on survival to time m . Formally $\Delta B^0(m) = f(S(m))$, and the (unknown) present value at time 0 of the payment process is

$$\int_{0-}^m e^{-\int_0^t r(s)ds} (-\pi I(t) dt + dN(t)) + e^{-\int_0^m r(\tau)d\tau} I(m) f(S(m)) \quad (26)$$

What is the financial value of this present value and what is the equivalence premium? Questions of this type were first approached with financial methods in [2] and since then by several other financial economists and insurance mathematicians [1]. To formalize the standard answer, we introduce two filtrations (see **Filtrations**) and corresponding measures generated by insurance risk and financial risk, respectively. Formally, $\mathcal{F}^Z(t) = \sigma(Z(s), 0 \leq s \leq t)$ and $\mathcal{F}^S(t) = \sigma(S(s), 0 \leq s \leq t)$ such that $(\Omega^Z, \mathcal{F}^Z, P^Z)$ and $(\Omega^S, \mathcal{F}^S, P^S)$ form two filtered probability spaces from which we can construct the filtered product probability space $(\Omega^Z \times \Omega^S, \mathcal{F}^Z \otimes \mathcal{F}^S, P^Z \otimes P^S)$. The standard answer to the valuation problem above is then to take a product measure combining the objective measure P^Z with respect to insurance risk in Z and some martingale measure (see **Equivalent Martingale Measures**) Q^S with respect to financial risk in S , that is,

$$\begin{aligned} E^{P^Z \otimes Q^S} & \left[\int_{0-}^m e^{-\int_0^t r(s)ds} (-\pi I(t) dt + dN(t)) \right. \\ & \left. + e^{-\int_0^m r(\tau)d\tau} I(m) f(S(m)) \right] \\ &= \int_{0-}^m e^{-\int_0^t (r(s) + \mu(x+s))ds} (-\pi + \mu(x+t)) dt \\ &+ e^{-\int_0^m (r(s) + \mu(x+s))ds} E^{Q^S} [f(S(m))] \quad (27) \end{aligned}$$

If the martingale measure is unique, so is the financial value of the payment process and the equivalence premium is obtained as in Example 1

by equating the financial value to zero and isolating π . It is a delicate issue to argue for equation (27) to be the “correct” value. It is clear that one somehow uses the diversification argument for the insurance risk and the no arbitrage argument for the financial risk. However, to make this precise, it takes arguments from incomplete markets pricing typically based on quadratic hedging or no asymptotic arbitrage approaches. Optimal investment is also an issue since, in general, no investment strategy hedges (see **Hedging**) the payment process for any outcome of the stochastic lifetime. In fact, parts of the development of quadratic hedging approaches (see [17] and references therein) are directly inspired by insurance applications in general and to life insurance payment processes in particular, [10, 11, 16].

The statewise reserves introduced above generalize to reserves for more general future payments. In the case of a Markov model for S , these are characterized by deterministic differential equations that generalize Thiele’s differential equation (16) [18].

Second, the transition intensities in the process Z move not only over age but also over calendar time in the sense that a mortality intensity for an x -year old is not necessarily the same in two different calendar years. If these movements are stochastic, this also creates dependence between policy holders and, thereby, between the payment processes written on their lives, and the Markov property of Z is lost. This is clear since the prospects of an insured’s life not only depends on his/her state of health but also on the historical demographic development that is common for all insured.

There are different approaches to the modeling of, for example, mortality intensities. These are typically either sociobiologically flavored or financially flavored. By sociobiological flavor we mean that the starting point for the modeling is the biological, medicinal, and sociological sources of uncertainties. If, say, the future invention of a particular vaccine is expected to have a significant impact on the mortality intensity, then one should try to predict the finding of such a vaccine. By financial flavor we mean that the main source of inspiration is modeling of the short rate of interest. The benefits of such an inspiration are clear when comparing the survival probability $e^{-\int_0^t \mu(s)ds}$ with a discount factor $e^{-\int_0^t r(s)ds}$. If we assume some kind of affine mortality intensity model, we achieve particularly simple expressions for, for

example, the expected survival probability,

$$E \left[e^{-\int_0^t \mu(s)ds} \right] \quad (28)$$

Such particularly simple expressions are appealing but suffer from mainly two disadvantages: it is difficult to motivate by sociobiological arguments that Vasicek or CIR (see **Cox–Ingersoll–Ross (CIR) Model**) model behavior should be present in mortality rates, and it is difficult to generalize the modeling advantages from the survival model to a multistate model.

The main challenge in stochastic modeling of the mortality intensity is the financial valuation of the demographic risk in a given model. Demographic risk is clearly nondiversifiable since the same mortality intensity hits a whole population or portfolio of insured. Is it priced by the financial market then? From the beginning of the millennium, there have been a few attempts by participants in the financial market to form a market for mortality derivatives. The idea is to involve the rest of the financial market, in addition to insurers and reinsurers, in taking part in mortality risk. The motivation for the investors is diversification since mortality intensities are not perfectly correlated with classical financial market risk. There are a lot of delicate questions concerning institutional and contractual design of products in such a market in addition to the modeling issues mentioned above. These questions are not so far answered sufficiently well by neither the market nor the academicians working in the field and, therefore, such a market is not flying yet. The prices in such a possible market place would give hints concerning the valuation of a survival probability, for example, under which probability measure (martingale measure) the expectation in equation (28) should be taken in order to form a market price. However, so far, the market is not sufficiently rich of assets and liquid to be really informative. See [3] for a review of the challenges of mortality risk.

The Deterministic Interest Rate Assumption

If this is not fulfilled we cannot, in the first place, say anything certain about the value at time t of one unit paid at time $u > t$. However, if there exists a sufficiently rich market of risk-free bonds, then we

can say something: if at time t we have access to a risk-free zero-coupon bond (see **Bond**) maturing at time u , then the value of that bond, denoted by $P(t, u)$, is the only value of the payment of one unit at time u that prevents arbitrage. From bond market theory, it is known that the zero-coupon price can be represented as the conditional expected value of the stochastic discount factor under an equivalent martingale measure Q^r derived from the price processes of the bond market. The question is, how can we use the bond market to update the valuation formula

$$E \left[\int_{0-}^n e^{-\int_0^t r(s) ds} dB(t) \right] \quad (29)$$

Here, the independence between payment processes does not carry over to the independence of present values in the following form:

$$\int_{0-}^n e^{-\int_0^t r(s) ds} dB(t) \quad (30)$$

since it is the same interest rate process that hits all policies. Again, we can take a product measure, now combining the objective measure P^Z with respect to insurance risk in Z and some martingale measure Q^r with respect to financial risk in r , and form the expectation

$$E^{P^Z \otimes Q^r} \left[\int_{0-}^n e^{-\int_0^t r(s) ds} dB(t) \right] \quad (31)$$

If the payments are in nominal terms, that is, independent of market risk including interest rate risk, this formula reduces to

$$E^{P^Z} \left[\int_{0-}^n P(0, t) dB(t) \right] \quad (32)$$

Again, the considerations apply: we cannot motivate equation (32) by either diversification or the no arbitrage principle but must rely on a combination of the two, introducing, for example, quadratic hedging in incomplete markets pricing and/or no asymptotic arbitrage arguments. No bond portfolio hedges the payment processes for all outcomes of Z , so the bond portfolio must reflect some optimization criterion.

What Can Finance Learn from Life Insurance: An Example

After a section about “what finance has done for life insurance”, we partly balance out things by a remark

on “what life insurance has done for finance.” Taking Figure 1 to represent the life history of a corporate rather than that of a human being, we have a simple credit risk model and in equation (2) a formalization of simple single-name credit risk derivatives. The default hazard rate μ is, however, usually then modeled as a stochastic process, depending on some underlying macroeconomic variables or processes creating cross-corporate dependence similar to the dependence between life histories of policy holders. Following this idea and replacing in Figure (3) the husband by Corporate A and his wife by Corporate B, we have a simple two-name model. In the payment process (9), we have formalized simple two-corporate credit risk derivatives. This model can from there be generalized to an arbitrary number of corporates. The cost of an exploding number of states and intensities as the number of corporates increases can be dealt by using appropriate cross-corporate homogeneity assumptions.

Figure (3) illustrates three sources of dependence playing distinct roles in the dependence modeling and in the calculation of expected values. One type of dependence between the two corporates exists, as mentioned in the previous paragraph, even if $\mu^{02} = \mu^{13}$ and $\mu^{01} = \mu^{23}$, but these intensities are functions of the same underlying economic processes. Then the corporates are dependent by being part of the same economy (or in the human life model by the two spouses being part of the same generation). Stronger dependence is present if, in addition, $\mu^{02} \neq \mu^{13}$ and/or $\mu^{01} \neq \mu^{23}$. The so-called positive contagion, for example, $\mu^{13} > \mu^{02}$, appears if, for example, there is some kind of contractual relation between the corporates (or in the human life model if, upon the death of his spouse, the widower tends to die from loneliness and isolation). The so-called negative contagion, for example, $\mu^{23} < \mu^{01}$, appears if, for example, the two corporates are competing and the surviving corporate wins market shares after the default of the other (or in the human life model if, upon the death of her spouse, the widow finds a young lover and lives out her second youth). Even stronger dependence is present if we, in addition, allow for a transition from state 0 to state 3. The so-called joint default appears if the corporates are so closely connected, for example, through some mother–daughter relationship, that one credit risk event draws down both corporates simultaneously (or in the human life model, if both spouses in

the married couple are sitting in the same lethally crashing car.)

Note that here the dependence is introduced in a dynamic way such that one clearly sees what is going on. The valuation of payment processes and fairness principles studied in this section carry over directly to dynamic valuation of involved multicorporate credit risk derivatives. Furthermore, nondiversifiable risk is probably less of a problem here, since much of the macroeconomic risk driving default intensities are actually priced by the market, for example, interest rate risk. The dynamic atomic modeling has some advantages over the usual copula approach to dependence modeling that aggregates static effects by the cost of opaqueness [7].

Design of Payment Streams

With-profit Life Insurance

On the one hand, the policy holder is interested in protecting buying power upon insurance events rather than nominal values. On the other hand, the insurance company is not necessarily interested in taking on nondiversifiable risk. Thus, the parties have delicate interests in sharing this risk, and this risk sharing takes many different institutional and contractual forms. In the traditional method for risk sharing, the payments finally paid are a consequence of the contract and the institutional management within certain regulatory constraints. The idea is, in the first place, to charge nominal premiums that are sufficiently high to cover nominal benefits under all possible outcomes of the economic–demographic environment. The surplus created by such a prudent payment stream belongs to the policy holder and should be redistributed as dividend payments to policy holders. The investment strategy and the redistribution are chosen at the discretion of the insurance company within a set of regulatory requirements.

The traditional way of forming the prudent nominal payment stream is to put up a set of artificial assumptions on the transition intensities μ^{jk*} and the interest rate r^* , thereby forming the so-called technical basis, representing some kind of worst-case scenario. Now the nominal payment stream B is settled in accordance with the equivalence principle under these artificial assumptions, that is, fulfilling

$$E^* \left[\int_{0-}^n e^{-\int_0^t r^*(\tau) d\tau} dB(t) \right] = 0 \quad (33)$$

where E^* denotes expectation with respect to the measure under which the transition intensities are given by μ^{jk*} . Under the technical basis, the independence assumption is fulfilled by construction, since the payments are nominal and all transitions intensities are deterministic such that Z is Markov under the technical measure. In addition, under the technical basis, the deterministic interest rate assumption is fulfilled by construction. Thus, since Condition 1 is fulfilled, the expectation on the left-hand side of equation (33) expresses a financial value, however, under the technical assumptions.

The surplus is created when capital gains different from r^* are realized and real transitions different from the ones expected through μ^{jk*} are experienced. This surplus is redistributed as dividend payments. We introduce a dividend payment process D with a structure similar to the one presented for B in equation (9). However, here we emphasize that the dividend payment process is not adapted to the filtration $\mathcal{F}^Z$ generated by Z , as is B in this case, but adapted to a larger filtration $\mathcal{F}^Z \vee \mathcal{F}^Y$, where $\mathcal{F}^Y$ is generated by realized capital gains and realized intensities. Now, what can we require from such a dividend payment process for the policy to be fair?

The classical approach is first to note that if the capital gains process and the transition intensities were known up to time n , this would be as working under Condition 1, and we could put up the usual equivalence principle. This observation inspires to an equivalence formula where the equivalence is required given the economic–demographic development, that is,

$$E \left[\int_{0-}^n \frac{1}{G(t)} d(B + D)(t) \middle| \mathcal{F}^Y(n) \right] = 0 \quad (34)$$

where G is the portfolio value corresponding to a self-financing investment strategy chosen by the insurance company. This means that all economic–demographic risk coming from the payment process B is returned to the policy holder through the payment process D . One can view this approach as careful risk management by design of the contract. This approach is discussed in [14].

The modern approach, inspired from mathematical finance, is actually to allow for an exchange of economic–demographic risk as long as this risk is priced in accordance with the market. This gives rise

to a substantial relaxation of equation (34) into

$$E^{P^Z \otimes Q^Y} \left[\int_{0-}^n e^{-\int_0^t r(s)} d(B + D)(t) \right] = 0 \quad (35)$$

This method does not necessarily return all economic–demographic risk to the policy holders but leaves parts of it at the insurer who is, in return, appropriately paid for this risk through the valuation measure Q^Y . There are, however, two main challenges in replacing equation (34) by equation (35): first, there is no (sufficiently rich and liquid) market to make the Q^Y measure unique with respect to demographic risk. Second, in the classical approach (34), all the risk management has been taken care of by the design of the contract. Introducing equation (35), risk management also means optimal decision making during the terms of the contract, for example, through optimal investment in incomplete markets. This approach is taken in many publications in the area, see the textbook [11] and references therein.

The insurance companies decide on the dividend process and the investment strategy to which it is adapted within certain constraints given by the contractual, institutional, and regulatory environment. There are, however, substantial regional and institutional differences in how this decision is constrained and made around the world. In addition, given the payment process D , there are differences in how this payment process materializes into payments experienced by the policy holders. In other words, these dividends are not necessarily paid out in cash. More often they are kept within in the insurance company but assigned to the policy holder who will then, in return, receive the so-called bonus payments in connection with either future premium payments and/or benefit payments in the payment process B . Here, we describe two of the more important arrangements. The first arrangement is important due to its major role in the UK/US tradition in the past, but during these decades it is partly superseded by the second arrangement that has a long tradition in the continental Europe.

In pension funding, the contract is part of an employment contract: the employer pays the premiums and the employee receives the benefits. The benefits are typically not nominal but rather linked to the policy holder's salary or some salary index. In general, prudent technical assumptions give rise to a positive and increasing dividend payment stream

that is experienced by the employer as a current or future discount in the premium level. However, if at all, one is not so concerned about prudence because a negative surplus can be filled by paying out negative dividends in terms of increasing current or future premiums paid by the employer. This arrangement splits the financial–demographic risk between the insurance company (pension fund) and the employer, whereas the employee goes free (apart from salary risk). This class of arrangements is called *defined benefits (DBs)* since the benefits are determined initially (possibly in terms of the salary), whereas the future premiums are unknown to the employer and will go up or down, respectively, when a negative or positive surplus is returned.

In with-profit life insurance, the contract is either a private contract or part of an employment contract. The employee or the employer pays the premium and the employee receives the benefits. Here, in contrast, the premiums are nominal or linked to some salary index. Sufficiently prudent technical assumptions give rise to a positive and increasing dividend payment stream that is experienced by the employee as a current or future bonus benefit level. One is here, in contrast, indeed concerned about prudence because a negative surplus can typically not be returned to the policy holder who is contractually protected from decreasing benefits: these are considered as binding minimum guarantees. The financial–demographic risk is shared between the policy holder who receives unknown benefits and the insurance company who bears the risk that the surplus becomes negative, whereas the employer goes free. This class of arrangements is called *defined contributions (DCs)* since the contributions (premiums) are determined initially (possibly in terms of the salary), whereas the future benefits are unknown to the employee (but often constrained downward by minimum guarantees).

It is clear that understanding the mathematics of finance in general and no arbitrage valuation in particular has played a crucial role in replacing the fairness constraint (34) by the fairness constraint (35). This replacement has given the involved parties, that is, policy holders typically represented by regulators, investors, and insurance companies, access to measuring and appropriately evaluating the exchanged risk. Note, however, that part of this risk is neither diversifiable nor hedgeable and therefore there is still some ambiguity left in the fairness criterion (35),

which is not present in equation (34). Also note that valuation is closely connected to existence of efficient hedging strategies—strategies that may be difficult to follow for leading insurance companies and pension funds due to regulatory restrictions and, more importantly, from a real economic point of view—these funds are often large investors in the sense that their actions in the market have adverse feedback effects in market prices.

Unit-linked Life Insurance

Unit-linked life insurance has partly replaced the traditional contracts described above, in particular in the private market. The idea comes from the US market and is making up an increasing part of the private market also in Europe with considerable regional differences, though. The idea is to formalize the adaptation to the economic–demographic environment explicitly in the contract in such a way that the investment strategy can be chosen at the discretion of the policy holder rather than the insurance company.

In pure unit-link insurance, that is, without any form of guarantee, all risks from the investment are eventually returned to the policy holder in one way or another. Then we can naturally take the counterpart to the equivalence criterion (34) and require equivalence of the payment process B ,

$$E \left[\int_{0-}^n \frac{1}{G(t)} dB(t) \middle| \mathcal{F}^Y(n) \right] = 0 \quad (36)$$

where G is the portfolio value corresponding to a self-financing investment strategy chosen partly by the policy holder. By multiplication of $G(n)$, which is $\mathcal{F}^Y(n)$ -measurable, and splitting up the integral, one sees that this is equivalent to the following settlement of the final lump sum payment:

$$\begin{aligned} E \left[\Delta B^{Z(n)}(n) \middle| \mathcal{F}^Y(n) \right] \\ = -E \left[\int_{0-}^{n-} \frac{G(n)}{G(t)} dB(t) \middle| \mathcal{F}^Y(n) \right] \end{aligned} \quad (37)$$

This relation restricts the terminal lump sum to finally make up for all movements on capital gains and transition intensities in the past. For this relation to hold, it is sufficient to formalize the payment process by

$$dB(t) = G(t) dB^*(t) \quad (38)$$

where $B^*(t)$ is a nominal payment process fulfilling the relation

$$E \left[\int_{0-}^n dB^*(t) \right] = 0 \quad (39)$$

In pure unit-link insurance, the (risk-minimizing) investment strategy implemented by the insurance company coincides essentially with the investment strategy stipulated in the contract.

Such an insurance contract is not provided in practice due to legislative constraints and the policy holder's demand for specification of guaranteed levels of premiums and benefits, typically nominal, that protect the policy holder from large capital losses. Such features introduce a genuine sharing of risk between the policy holder and the insurance company, and the criterion (36) is too tight. We can relax equation (36) by introducing the counterpart to equation (35) and require that the payment process B fulfills

$$E^{P^Z \otimes Q^Y} \left[\int_{0-}^n e^{-\int_0^t r(s)} dB(t) \right] = 0 \quad (40)$$

For example, let us say that the terminal lump sum payment given in equation (37) is floored off at some guarantee level K . This guarantee must be compensated, for example, by specifying that only a proportion a of the sum is paid out if it is larger than K , that is,

$$\begin{aligned} E \left[\Delta B^{Z(n)}(n) \middle| \mathcal{F}^Y(n) \right] \\ = \max \left(-a E \left[\int_{0-}^{n-} \frac{G(n)}{G(t)} dB(t) \middle| \mathcal{F}^Y(n) \right], K \right) \end{aligned} \quad (41)$$

Looking closer at this, the terminal payment is some kind of delicate Asian option on G . Now, financial mathematics helps us in calculating fair pairs of a and K such that equation (40) is fulfilled. Such pairs will depend on the riskiness in the portfolio underlying G . The pair $(1, -\infty)$ is one example, corresponding to equation (37), that does not depend on the investment portfolio, though. In such more advanced types of unit-link insurance, the (risk-minimizing) investment strategy implemented by the insurance company does not essentially coincide with the investment strategy chosen by the policy holder but contains some investment in or hedging of the embedded derivatives.

Management of Payment Streams

In the section Design of Payment Streams, we set the framework for the design of the payment streams. Furthermore, we discussed fairness constraints. Within the fairness constraints, there are a series of decisions to be made by the insurance company and/or the policy holder. In this section, we focus on these decisions. In with-profit life insurance and pension funding, there are two decision processes of paramount interest: the investment decisions underlying G and the dividend payment stream D .

We form the surplus X at time t as the assets at time t minus the liabilities at time t with respect to the contract or portfolio of contracts in focus. The assets are the payments to the insurance company (premiums less benefits) in the past accumulated with capital gains. The liabilities are some measure of the future obligations in the payment process B , here denoted by $V(t)$. Thus,

$$X(t) = - \int_{0-}^t \frac{G(\tau)}{G(s)} d(B + D)(s) - V(t) \quad (42)$$

From our analysis in the section Valuation of Payment Streams, we have several candidates for the liabilities to be plugged in: the classical liability is the technical reserve

$$E^* \left[\int_t^n e^{-\int_t^s r^*(\tau) d\tau} dB(s) \middle| Z(t) \right] \quad (43)$$

which is the present value of future payments under the same artificial assumptions as the ones used in the equivalence principle. This ensures that, by the equivalence principle, the surplus prior to inception is equal to 0, that is, $X(0-) = 0$. A more realistic estimate of the future obligations is a market consistent valuation along the lines of equation (32) of the future payments conditional on all information up to time t :

$$E^{PZ} \left[\int_t^n P(t, s) dB(s) \middle| Z(t) \right] \quad (44)$$

Anyway, the surplus will evolve according to the investment and dividend decisions made in the past. In fact, the surplus can be considered as the policy holder's extra wealth, in excess of V , which is managed by the insurance company. Since the investment strategy can be parameterized as an investment strategy for the surplus itself, this investment–dividend

problem is a delicate version of the classical investment–consumption problem known from finance. It is certainly a nonstandard version due to a series of particularities (related to financial topics mentioned in brackets): (i) the decision maker and the consumer do not coincide since the dividends go to the policy holder while the investment–dividend decisions are made by the insurance company (principal agent problem); (ii) usually, the dividends are not paid out as cash but transferred to a future payment stream (habit formation); (iii) obligations are nonhedgeable due to diversifiable death risk and nondiversifiable mortality risk (nonhedgeable income process); (iv) there are regional solvency constraints on the surplus—varying in strictness and underlying valuation principles (intermediate constraints on wealth); (v) there are regional constraints on investment and surplus redistribution strategies (intermediate constraints on investment and consumption); (vi) usually, the surplus is accounted for on (sub)portfolio level rather than individual level and the portfolio members have possibly inhomogeneous attitudes to risk; and (vii) short-fall risk due to nonhedgeable obligations or aggressive investment decisions is borne by the equity holders who should be appropriately paid for it.

The list of particularities is all parts of the subject matter of ALM, which is essential in modern mathematics of life insurance and its merger with parts of mathematical finance, including incomplete market valuation, liability-driven investments, constrained asset allocation, and strategic asset allocation. These areas of finance have gained momentum from their applications in life insurance and versions of these problems stemming from practical problems in the insurance market continue to challenge asset managers both on the theoretical and the practical side.

With the prevalence of unit-link insurance comes the importance for the policy holders to make good investment decisions and for the insurance companies to advise them in doing so. At first glance, this is a classical personal finance problem of optimal investment of pension savings, with or without uncertain lifetime. However, the appearance of genuine insurance elements in the contract, that is, financial protection against life history events, brings to the surface a more delicate process of decision making. This includes the financial protection bought throughout

life in terms of insurance payments: given the financial situation at time t , what is the best death sum, disability sum/annuity, and unemployment sum/annuity to buy? Optimal decisions are naturally influenced by the market price of risk and risk aversion of the policy holder, as is the investment decision in classical personal finance. However, the market price of risk is not necessarily easy to deduct from a market offering contracts with nonexplicit participation features and constraints in a heavily regulated environment. And should risk aversion with respect to life history risk be parameterized in the same way as risk aversion with respect to financial risk?

Clearly, the formulation of the optimization problem is much more involved in the area of personal finance and insurance than in the area of pure personal finance. Ambiguity in the way the optimization problem should be formulated at all and the opaque insurance market in which the decisions are to be taken contribute to a complication of the subject matter. However, it also turns out facilitating in some respects to introduce access to the insurance market: it is by now well-accepted that human wealth, that is, the financial value of future labor earnings, is an important asset in personal decision making. This explains partly the rationale of life cycle investment saying that younger people should hold a larger proportion of their financial assets in risky investments than should older people. However, uncertainties in future earnings in general and the risk of losing the human wealth in an insurance event—for example, disability or unemployment—make the human wealth difficult to assess. The introduction of an insurance market and insurance decisions has a completing effect on the market that makes the assessment of human wealth less ambiguous.

In the literature, the approach to personal finance and insurance go in two distinct directions: one direction is inspired from ruin considerations and formulates the optimization problem in terms of the probability of life time ruin in the sense of ever living below some defined level of poverty [9]. Another direction is inspired from personal finance and formulates the optimization problem in terms of expected utility of future consumption across life history events and uncertain lifetimes. This direction was initiated in [15] and recent contributions are [8, 12].

Stochastic Control in Insurance

Classification of Models

The stochastic control problem in insurance can be classified according to the type of models used to describe the *surplus* or the *risk* process (see **Insurance Risk Models**), the particular controls that are allowed, and the nature of the objective function.

Modeling of the Surplus

In the classical *Cramér–Lundberg* model, the risk process is modeled by a compound Poisson process

$$R(t) = R(0) + pt - \sum_0^{A(t)} U_i \quad (1)$$

where $A(t)$ is the Poisson process of the incoming claims, whose intensity β without loss of generality can be set to 1, the i.i.d. sequence U_i represents the sizes of the successive claims and p is the premium rate with $p = (1 + \eta)EU$, with η being the *relative safety loading*. If one considers a sequence of such models with $R^n(0) = xn^{1/2}$ and $\eta^n = \mu n^{-1/2}$, then $R^n(nt)n^{-1/2}$ converges weakly to a Brownian motion with drift μ and diffusion coefficient $\sigma = [EU^2]^{1/2}$.

Reinsurance

The risk control in either of such models is done by way of *reinsurance* (see **Reinsurance**). This is a contract that the *cedent* (the original insurance company) makes with the reinsurance company so that the reinsurance company pays a part or all of each of the incoming claims in exchange for the portion of the premiums coming to the cedent. The cedent makes a decision on the *retention level* a , and the size of each claim is reduced from U_i to U_i^a , while the premium rate is simultaneously reduced from p to p^a ; the precise meaning of this is different for different types of the reinsurances involved. The following are the most common types of reinsurances considered in the literature:

- Proportional reinsurance. $U^a = aU$, $0 \leq a \leq 1$.
- Excess-of-loss reinsurance. $U^a = U \wedge a$, $0 \leq a < \infty$.

- *XL-reinsurance*. $U^a = U \wedge M + (U - M - L)^+$. Here $a = (M, L)$ is described by two parameters $0 \leq L, M < \infty$, with M being called the retention level and L being called the *limit*.

When the type of the reinsurance is fixed, the premium rate p^a depends on the premium calculation principle:

- Expected value principle. $p^a = p - (1 + \eta_1)E(U - U^a)$, where η_1 is the safety loading of the reinsurer.
 - *Cheap reinsurance*. $\eta_1 = \eta$. In this case, $p^a = (1 + \eta)E(U^a)$.
 - *Noncheap reinsurance*. $\eta_1 > \eta$.
- Variance principle. $p^a = p - [E(U - U^a) + p_1 \text{var}(U - U^a)]$

Given the reinsurance scheme, once the level a is chosen, the dynamics of the surplus process $R^a(t)$ will be governed by equation (1) with U replaced by U^a and p replaced by p^a . If one makes a diffusion approximation then the limiting process will be a linear diffusion with drift μ^a and diffusion coefficient σ^a , while $\sigma^a = E[(U^a)^2]^{1/2}$ is the same as before. Further, μ^a is equal to the difference between the premium rate per unit time and the expected losses per unit time.

- Cheap proportional reinsurance. $\mu^a = a\mu$, $\sigma^a = a\sigma$.
- Noncheap proportional reinsurance. $\mu^a = \mu - (1 - a)\lambda$, $\sigma^a = a\sigma$, $\lambda > \mu$.
- Excess-of-loss reinsurance. $\mu^a = \int_0^a (1 - F(x)) dx$, $\sigma^a = [\int_0^a 2x(1 - F(x)) dx]^{1/2}$.

In stochastic control models, the reinsurance is dynamically controlled, that is, $a = a(t)$, where $a(t)$ is a process adapted to the information filtration. Other controls used in the insurance optimization models are given below.

Dividend Control

In the problems where the objective is to maximize the present value of the dividends, the latter is controlled. The corresponding control is described by an increasing functional $L(t)$ which is the cumulative amount of dividends paid out up to time t . From the definition, it follows that $L(t)$ is an increasing

right-continuous process with $L(0-) = 0$. As with any control functional, it should be adapted to the information filtration, and in addition we require that for any t (deterministic or random) $L(t) - L(t-) \leq R(t)$, where $R(t)$ is the value of the surplus at time t .

Investment Control

In case the models allow the surplus to be invested in the financial market we have a third control $b(t)$ representing the amount invested in the risky asset at time t (for simplicity, we consider here only the Black–Scholes financial market (see **Black–Scholes Formula**) with one risky asset; the generalization to multiple assets and other markets is obvious).

Model Formulation

and the Hamilton–Jacobi–Bellman Equation

Any stochastic control model starts with a probability space $(\Omega, \mathcal{F}, P)$ endowed with a filtration (see **Filtrations**) $\mathcal{F}_t$, $t \geq 0$ and a process $\sum_{i=1}^{A(t)} U_i$ (in the case of Cramér–Lundberg modeling) or a standard Brownian motion $w(t)$ adapted to $\mathcal{F}_t$. A control π consists of a triple $(a(\cdot), b(\cdot), L(\cdot))$ of functionals adapted to the information filtration $\mathcal{F}_t$. If it satisfies the previously mentioned restrictions, then the control is *admissible*. Once the control π is chosen, then in the case of the Cramér–Lundberg model the dynamics of the controlled surplus process becomes

$$\begin{aligned} dR(t) &= p^{a(t)} dt - dN^{a(t)}(t) \\ &\quad + b(t) dS_1(t)/S_1(t) + (R(t) \\ &\quad - b(t)) dS_0(t)/S_0(t) - dL(t) \end{aligned} \quad (2)$$

$$R(0) = x \quad (3)$$

Here, $dN^a(t)(t) = U^{a(t)} 1_{A(t)-A(t-)=1}$. In the case of the diffusion approximation, the surplus is governed by

$$\begin{aligned} dX(t) &= \mu^{a(t)} dt + \sigma^{a(t)} dw(t) \\ &\quad + b(t) dS_1(t)/S_1(t) + (X(t) \\ &\quad - b(t)) dS_0(t)/S_0(t) - dL(t) \end{aligned} \quad (4)$$

$$X(0) = x \quad (5)$$

with $S_0(t)$ and $S_1(t)$ being the price process for risk-free and risky asset, respectively.

Objectives

We describe below the two most popular objectives that are studied in the optimization models in insurance.

- *Ruin probability minimization.* In this case, the third control related to dividends payouts is not present and $\pi = (a(\cdot), b(\cdot))$. The stopping time τ , which is the hitting time of $(-\infty, 0)$ by the surplus process (that is the first time when the surplus process becomes negative) is called the *ruin time* (see **Ruin Theory**). With each control π , a *performance index* $J_x(\pi) = P(\tau < \infty)$ is defined, where x stands for the initial surplus. The objective is to find the *value function* $V(x) = \inf_{\pi} J_x(\pi)$ and the associated *optimal control* π^* , such that $V(x) = J_x(\pi^*)$.
- *Dividend optimization.* The performance index in this case is related to the expected cumulative present value of the total dividend payouts until the time of bankruptcy. If there is no setup cost each time the dividend payments are initiated and the payments can be paid in a continuous manner, then $J_x(\pi) = E \left[\int_0^\tau e^{-ct} dL(t) \right]$, where c is the discount rate. The value function and the optimal control are defined as $V(x) = \sup_{\pi} J_x(\pi)$ and $J_x(\pi^*) = V(x)$.

In the models with a setup cost, $L(t) = \sum_{i=1}^\infty \xi_i 1_{\zeta_i \leq t}$ where ζ_i is an increasing sequence of stopping times, corresponding to the times when the dividends are paid out and ξ_i is a positive $\mathcal{F}_{\zeta_i}$ -measurable random variable representing the amount of dividends paid out at the times ζ_i . In this case, $J_x(\pi) = E \left[\sum_{i=1}^\infty e^{-c\zeta_i} g(\xi_i) \right]$, where $g(y)$ is a function showing the amount of dividends that reaches shareholders, if y of the surplus is used for the dividend distribution, for example, $g(x) = x - K$.

Optimality Equations and the Optimal Control

For any fixed pair a, b , let $R^{a,b}$ or $X^{a,b}$ be the process defined by equation (2) or (4), respectively, with $a(t) \equiv a$, $b(t) \equiv b$ and $L(t) \equiv 0$, and let $\mathcal{L}^{a,b}$ be the *infinitesimal generator* of this process. Then dynamic programming shows that if $V(x)$ is a C^2 function, then in the case of ruin probability minimization it satisfies the Hamilton–Jacobi–Bellman equation:

$$\min_{a,b} \mathcal{L}^{a,b} V(x) = 0 \quad (6)$$

In diffusion models, equation (6) is a fully nonlinear second-order differential equation, while in the Cramér–Lundberg case it is a second order integro-differential equation. One of the boundary conditions for equation (6) is $V(\infty) = 0$, and the second boundary condition is at the point 0. For the diffusion case, it is $V(0) = 1$, while in the Cramér–Lundberg case it is $\gamma V(0) + \delta V'(0) = 0$, with γ and δ determined from the exogenous parameters of the problem. The argmin $(A^*(x), B^*(x))$ of the left-hand side of equation (6) provides the *optimal feedback control functions*, which when substituted into equation (2) or (4) as $(A^*(R(t)), B^*(R(t)))$ or as $(A^*(X(t)), B^*(X(t)))$ in the place of $a(t)$ and $b(t)$ results in the stochastic differential equation whose solution yields the optimal surplus process and the optimal control as a function of time.

For the dividend optimization problem, the Hamilton–Jacobi–Bellman equation for the value function takes on the form

$$\max_{a,b} [\max \mathcal{L}^{a,b} V(x) - cV(x), \mathcal{M}V(x)] = 0 \quad (7)$$

The operator $\mathcal{M}$, in the case of continuous dividend payments, is the first-order differential operator $1 - V'(x)$, while in the case of discrete payments it is of a quasi-variational form $\max_{y < x} [V(x) - V(y) + (x - y) - K]$. The boundary conditions at ∞ are of a polynomial growth type. The boundary condition at 0 for the Cramér–Lundberg model is similar to the ruin minimization case, and for the diffusion model it is $V(0) = 0$. The optimal feedback risk and investment control functions are determined the same way as before, while the smallest point where the solution satisfies $\mathcal{M}V(x) = 0$ determines the level which the surplus under the optimal control should never exceed and reaching which triggers the dividends payments.

Bibliographical Remarks

A discrete time model of ruin probability minimization in which reinsurance and investment are present was considered in [16]. Ruin probability minimization in the Cramér–Lundberg case was studied [9–11]. For diffusion models, this problem was treated in [15, 17, 18, 20].

One of the first dividend maximization problems in the framework of the classical risk process was considered in [4] and [7]. There, the optimality of the

barrier strategy was stated. A dividend distribution model with the reinsurance control was studied in [3].

Dividend optimization in diffusion models with continuous dividend payouts was considered in [1, 2, 12–14]. An analysis of the model in which a setup cost leads to discrete optimal dividend payouts is done in [5].

Problems of optimal control of a pension fund were studied in [6] and [8]. The monograph [19] is a good source of the methods and techniques used in application of stochastic control in insurance. It also provides a comprehensive list of the literature.

MICHAEL TAKSAR

Esscher Transform

The *Esscher transform* has a long and remarkable history in actuarial science. Its origin can be traced back to the seminal work of a Swedish actuary, Esscher [7], whose motivation was to develop a flexible and convenient way to approximate the probability distribution of the aggregate claims of an insurance portfolio (see **Accumulated Claims**), an important problem in the classical risk theory. Bühlmann [1, 2] developed the Esscher premium calculation principle and showed that it is a particular case of an economic premium principle. Nowadays, the Esscher transform has applications in option valuation, asset allocation, and risk management, the so-called three pillars in quantitative finance.

Suppose $F(x)$ represents the probability distribution function of a nonnegative random variable X and θ denotes a real constant so that the moment generating function of X exists; that is,

$$M_X(\theta) := E[e^{\theta X}] < \infty \quad (1)$$

The Esscher transform $F(x, \theta)$ is defined as

$$F(x, \theta) := \frac{\int_0^x e^{\theta y} dF(y)}{M_X(\theta)} \quad (2)$$

Here, $F(x, \theta)$ is well defined since $M_X(\theta) < \infty$. $M_X(\theta)$ is a normalization constant to make $F(x, \theta)$ a probability distribution function.

The main idea of the Esscher transform is to define a new probability distribution function for X by adjusting the original distribution $F(x)$ of X using an exponential factor $e^{\theta y}$. In particular, for each given parameter θ , we associate it with a transformed probability distribution function $F(x, \theta)$ of X .

In this article, we focus on the applications of the Esscher transform in quantitative finance. For an excellent survey of the applications of the Esscher transform in actuarial science, see [14]. Here, we discuss the applications of the Esscher transform to option valuation and asset allocation (see **Merton Problem**). For the applications of the Esscher transform to risk management, see [12].

Application to Option Pricing

The pioneering work of Gerber and Shiu [8] used the Esscher transform for option valuation. Let $\{X(t); t \geq 0\}$ denote a stochastic process with stationary and independent increments and $X(0) = 0$. Assume that the force of interest or the risk-free interest rate r is a positive constant. For each $t \geq 0$, the random variable $X(t)$ has an infinitely divisible distribution. Let $S(t)$ denote the price of a non-dividend-paying risky asset at time t . Assume that

$$S(t) = S(0)e^{X(t)}, \quad t \geq 0$$

Here, $X(t)$ represents the continuously compounded return from the non-dividend-paying risky asset over the time horizon $[0, t]$.

Let $F(x, t)$ denote the probability distribution function of $X(t)$. Suppose $M_X(z, t)$ represents the moment generating function of $X(t)$; that is, $M_X(z, t) := E[e^{zX(t)}]$. The Esscher transform of the process $\{X(t); t \geq 0\}$ is also a process with stationary and independent increments. The probability distribution function of $X(t)$ defined by the Esscher transform with parameter θ is

$$F(x, t; \theta) := \frac{\int_0^x e^{\theta y} dF(y, t)}{M_X(\theta, t)} \quad (3)$$

The moment generating function of $X(t)$ evaluated under the probability distribution function $F(x, t; \theta)$ defined by the Esscher transform with parameter θ is

$$M_X(z, t; \theta) = \frac{M_X(\theta + z, t)}{M_X(\theta, t)} \quad (4)$$

By the fundamental theorem of asset pricing (see **Fundamental Theorem of Asset Pricing**) (see [10, 11]), to guarantee the absence of arbitrage (see **Arbitrage Strategy**) options should be priced by taking the expected discounted payoffs with respect to an equivalent measure under which the discounted stock price process $\{e^{-rt} S(t); t \geq 0\}$ is a martingale (see **Equivalent Martingale Measures**). Such a change of measure can be achieved using the Esscher transform in the following way. First, we look for a risk-neutral Esscher parameter θ^* such that

$$1 = e^{-rt} E^*[e^{X(t)}] \quad (5)$$

where $E^*[\cdot]$ represents expectation taken with respect to the probability distribution function $F(x, t; \theta^*)$. Equivalently, θ^* is the unique solution of the following equation (see [8]):

$$r = \ln[M_X(1, 1; \theta^*)] \quad (6)$$

Now, we consider a European-style option (see **Options: Basic Definitions**) with payoff $V(T)$ at maturity T . Then, the price of the option is

$$V(0) = E^*[e^{-rT} V(T)] \quad (7)$$

The Esscher transform provides a flexible and convenient way to price options under different parametric specifications of the return process of the underlying risky asset. It is also a convenient tool for option valuation under an incomplete market, in which there is more than one equivalent martingale measure and not every contingent claim can be hedged (see **Hedging**) perfectly. However, an important question arises. How does one justify an option price obtained from the Esscher transform in an incomplete market? Gerber and Shiu [8] showed that an option price arising from the Esscher transform can be obtained by solving a utility maximization problem of an economic agent with power utility. Bühlmann *et al.* [3, 4] provided justification for the use of the Esscher transform for asset pricing under general dynamics of the underlying risky assets. The novelty of the work of Gerber and Shiu is to highlight the interplay between actuarial and financial pricing, which is coined as an important research agenda in modern actuarial science (see [3]). Since the work of Gerber and Shiu [8], there has been much work on further exploring the use of the Esscher transform for option pricing.

Bühlmann *et al.* [3] introduced the conditional Esscher transform to price options under general semimartingales (see **Martingales**). Bühlmann *et al.* [4] adopted the Esscher transform in a discrete financial model and investigated the no-arbitrage theory of asset pricing. Chan [5] employed the Esscher transform to price options in a continuous-time financial model driven by Lévy processes (see **Exponential Lévy Models**). Yao [15] specified a forward-risk-adjusted measure and developed a consistent framework for pricing options on equities, interest rates and foreign exchange rates. Siu *et al.* [13] introduced the use of the Esscher transform for pricing options under a class of GARCH models with innovations having a general and flexible distribution. Elliott *et al.* [6]

considered the option pricing problem when the price dynamics of the underlying risky asset are governed by a Markov regime-switching model.

Asset Allocation

The Esscher transform can also be used to provide an elegant solution to the asset allocation problem [9]. Here, we outline the key results from Gerber and Shiu [9] under a complete securities market with a single primitive risky asset. Let $\{X(t); t \geq 0\}$ denote a Wiener process with “real-world” expected rate of return μ and diffusion coefficient σ ; that is, for each $t \geq 0$, $X(t)$ follows a normal distribution with mean μt and variance $\sigma^2 t$. Define a price kernel of the securities market by the Esscher transform as below:

$$\Lambda := \frac{e^{\theta^* X(T)}}{E[e^{\theta^* X(T)}]} \quad (8)$$

where, in this case, the risk-neutral Esscher parameter θ^* is given by

$$\theta^* = \frac{r - \sigma^2/2 - \mu}{\sigma^2} \quad (9)$$

Let $\beta := \theta^* \mu + (\theta^* \sigma)^2/2$. Then,

$$\Lambda = e^{\theta^* X(T) - \beta T} \quad (10)$$

Suppose Y denotes a random payment in the securities market at time T . Then, the price of the random payment at time 0 is $E[\Lambda Y]$. Consider an investor with initial wealth w and decision horizon T who buys the random payment Y . Then, the terminal wealth of the investor at time T is

$$W(T) = we^{rT} + Y - E[\Lambda Y] \quad (11)$$

This implies that

$$E[\Lambda W(T)] = we^{rT} \quad (12)$$

Now, we suppose that the investor has a risk-averse utility function (see **Utility Function**) $u(x)$ such that $u'(x) > 0$ and $u''(x) < 0$. The goal of the investor is to determine the terminal wealth $W(T)$, which maximizes the expectation $E[u(W(T))]$ subject to the budget constraint imposed by equation (12).

Gerber and Shiu showed that the necessary and sufficient condition for optimality is

$$u'(W(T)) = E[u'(W(T))]\Lambda \quad (13)$$

The necessary condition can be shown by a standard tool in actuarial science, namely, the variational argument (see [9]). The sufficient condition for optimality can be shown by exploiting the concavity of the utility function.

Let $m := E[u'(W(T))]$. Suppose I is an inverse of the marginal utility function u' . Since $u'' < 0$, I exists. Then, the optimal terminal wealth is

$$W(T) = I(m\Lambda) \quad (14)$$

By equations (12) and (14),

$$E[\Lambda I(m\Lambda)] = we^{rT} \quad (15)$$

Consider an exponential utility function as follows:

$$u(x) = -\frac{e^{-\alpha x}}{\alpha}, \quad x \in (-\infty, \infty) \quad (16)$$

where $\alpha > 0$ and $1/\alpha$ is the constant level of risk tolerance.

In this case, the optimal terminal wealth is given by

$$W(T) = we^{rT} + \frac{\theta^*[(r - \sigma^2/2)T - X(T)]}{\alpha} \quad (17)$$

Under the assumption of a frictionless and complete market, Gerber and Shiu [9] determined an optimal dynamic strategy by replicating a contingent claim related to the optimal terminal wealth $W(T)$. In particular, for the exponential utility function, Gerber and Shiu [9] obtained the following optimal amount invested in the risky asset at time $t \in [0, T]$ using the dynamic delta hedging argument:

$$\rho(t) = \left(\frac{\mu - r + \sigma^2/2}{\alpha\sigma^2} \right) e^{-r(T-t)} \quad (18)$$

Large Deviations

Modern large deviations theory, pioneered by Donsker and Varadhan [11], concerns the study of rare events, and it has become a common tool for the analysis of stochastic systems in a variety of scientific disciplines and in engineering. The theory developed by Donsker and Varadhan is a generalization of Laplace's principle and Cramér's theorem. Here we concentrate on applications to finance and risk management.

A wealth of monographs discuss the large deviations theory in detail; see, for instance, [8–10]. Here, we shall discuss applications to mathematical finance, including option pricing (*see Option Pricing: General Principles*), risk management (*see Risk Exposures; Risk Management: Historical Perspectives*), and portfolio optimization (*see Risk–Return Analysis; Merton Problem*). The reader may also consult [21], which includes details behind many of the topics touched upon here. Before discussing these applications, however, we provide a brief introduction to some basic concepts underlying the theory of large deviations.

Definition 1 *A sequence of random objects $(Z_n : n \geq 0)$ taking values on some topological space S satisfies a large deviations principle with rate function $(J(z) : z \in S)$, if for each Borel measurable set $A \in \mathcal{S}$*

$$\inf_{z \in A^\circ} J(z) \leq \lim_{n \rightarrow \infty} -\frac{1}{n} \log P(Z_n \in A) \leq \overline{\lim}_{n \rightarrow \infty} -\frac{1}{n} \log P(Z_n \in A) \leq \inf_{z \in \bar{A}} J(z) \quad (1)$$

and $J(\cdot)$ is nonnegative and upper semicontinuous. Here A° and $\bar{A}$ stand for the interior and closure of A , respectively.

Throughout this article, we assume that S is a Polish space (i.e., a separable, completely metrizable topological space). One can show that if a large deviations principle holds, then there exists a deterministic element $\tilde{z} \in S$ such that $Z_n \Rightarrow \tilde{z}$ (where $\Rightarrow$ denotes weak convergence). In many applications, S is a function space, so Z_n is a stochastic process and $\tilde{z}$ is the asymptotically most likely path.

A large deviations principle is intuitively interpreted as having the formal approximation

$$P(Z_n \approx z) \approx \exp(-nJ(z)) \quad (2)$$

for z outside a neighborhood of $\tilde{z}$. The previous approximation does not carry any rigorous meaning. Nevertheless, the formal use of equation (2) often allows to infer large deviations properties of stochastic systems that can be later justified rigorously using large deviations theory. The rigorous meaning behind equation (2) is given by Varadhan's lemma (see [8], p. 137), which states that, in the presence of a large deviations principle, for every continuous function $(F(z) : z \in S)$ bounded from below we have that

$$\log \frac{1}{n} E \exp(-nF(Z_n)) \longrightarrow -\inf_{z \in S} (J(z) + F(z)) \quad (3)$$

as $n \nearrow \infty$. Varadhan's lemma is a generalized version of Laplace's principle. Indeed, note that in view of representation (2), Varadhan's lemma makes perfect intuitive sense after applying Laplace's principle since

$$\begin{aligned} E \exp(-nF(Z_n)) &\approx \int \exp(-n(J(z) + F(z))) dz \\ &\approx \exp\left(-n \inf_{z \in S} (J(z) + F(z))\right) \end{aligned} \quad (4)$$

The solution to the optimization problem $\inf_{z \in S} (J(z) + F(z))$ is the so-called minimum energy path or optimal path. Formally, if we put $F(z) = \infty \times I_{A^c}(z)$, then $E \exp(-nF(Y)) = P(Y \in A)$ and if $\tilde{z} \notin A$ and regularity assumptions on the set A hold, Varadhan's lemma yields

$$P(Z_n \in A) \approx \exp\left(-n \inf_{z \in A} J(z)\right) \quad (5)$$

A related class of asymptotic approximations arises in the setting of dynamical systems with a small random perturbation, for instance,

$$\begin{aligned} dZ_\varepsilon(t) &= \mu(Z_\varepsilon(t)) dt + \varepsilon \sigma(Z_\varepsilon(t)) dB(t); \\ Z_\varepsilon(0) &= z_\varepsilon(0) \end{aligned} \quad (6)$$

assuming the necessary regularity conditions for the existence of a solution to the previous stochastic

differential equations (SDEs) driven by a standard Brownian motion $B(\cdot)$. Note that, formally, if we send $\varepsilon \rightarrow 0$ and assume that $z_\varepsilon(0) \rightarrow \tilde{z}(0)$, we obtain convergence of Z_ε to a deterministic dynamical system satisfying $\tilde{z}'(t) = \mu(\tilde{z}(t))$ given $\tilde{z}(0)$. Therefore, under appropriate conditions, one would expect the existence of a theory backing up approximations such as equation (2) given by an appropriate rate function $I(\cdot)$. Such a theory has indeed been developed, and it is known as the Freidlin–Wentzel theory (see, [8], p. 212 or [22], p. 129). The rest of this article concentrates on the application of the ideas of large deviations in finance.

Option Pricing

Direct Use of Large Deviations Approximations

Large deviations principles are applied in finance to develop approximations for option prices (see **Option Pricing: General Principles**). It is easier to explain the techniques with a simple example. Consider the problem of pricing a digital knock-in call option (see **Barrier Options**) with maturity time T under a *Black–Scholes* economy (see **Black–Scholes Formula**), in particular,

$$\alpha_T = P\left(\min_{0 \leq s \leq T} B(s) \leq -a, B(T) > b\right) \quad (7)$$

for some barrier values $a, b > 0$, where $B(\cdot)$ is a standard Brownian motion. This probability can be, of course, evaluated in closed form ([17, 18], or see equation 12 below), but we illustrate the use of large deviations theory here. We develop approximations that can be asymptotically validated when the time to maturity and the barriers are large. First, we embed the problem in a large deviations setting by introducing an appropriate scaling

$$\alpha_T = P\left(\min_{0 \leq u \leq 1} Z_T(u) \leq -c, Z_T(1) \geq d\right) \quad (8)$$

where $a = -Tc$ and $b = Td$, and $Z_T(u) = B(uT)/T$, $u \in [0, 1]$. The rate function of $Z_T(\cdot)$ is defined on the space $C_1 := C_1[0, 1]$ of absolutely continuous functions and takes the form

$$J(z) = \frac{1}{2} \int_0^1 \dot{z}(u)^2 du \quad (9)$$

Note that $Z_T \rightarrow \tilde{z} = 0$ uniformly in probability. A formal application of equation (2) combined with Laplace’s principle then yields

$$\alpha_T \approx \exp\left(-T \inf_{z \in A} J(z) + o(T)\right) \quad (10)$$

where

$$A = \{z \in C_1 : z(0) = 0, \min_{0 \leq u \leq 1} z(u) \leq -c, z(1) \geq d\} \quad (11)$$

One can then show directly using standard techniques from calculus of variations (applying Euler–Lagrange’s principle) that the optimal path is a piecewise linear function. Note that equation (2) also suggests that the optimal path is the most likely way in which the particular large deviations event, given by A , can occur. In our simple example one can directly evaluate such an optimal path by using the reflection principle. In particular, note that

$$\begin{aligned} \alpha_T &= P(B(T) > (2a + b)T) \\ &= P(Z_T(1) > 2c + d) \end{aligned} \quad (12)$$

which allows to conclude (again by reflection) that

$$z^*(t) = I(t \leq t^*)\theta_- + (\theta_+ - c)I(1 \leq t \leq t^*) \quad (13)$$

where $\theta_- = -(2c + d)$, $\theta_+ = -\theta_-$ and $t^* = c/(2c + d)$. Moreover, we have that $J(z^*) = (2c + d)^2/2$. It is important to note using equation (12) and elementary properties of the Gaussian density that

$$\alpha_T = \frac{\exp(-TJ(z^*))}{(2\pi)^{1/2} T^{1/2}} \quad (14)$$

as $T \nearrow \infty$. In particular, it is worth noting that the large deviations results such as equation (11) provide only rough approximations because no information is given about premultiplying terms like the factor $T^{-1/2}$, which appears in equation (14).

Enhancing Monte Carlo Simulations

As indicated above, large deviations approximations typically provide only logarithmic asymptotics (i.e.,

only the exponential rate of decay is identified without any additional information). Sharp asymptotics (i.e., asymptotics with information about premultiplying factors such as equation 14) can only be developed under an additional problem structure. We continue with our discussion on pricing issues in the context of **barrier options**; the option pricing described in the previous paragraph is just an example of one of many types that are possible. In evaluating barrier options, an important aspect relates to the calculation of exit probabilities. For instance, in [5] such calculations are treated combining both Monte Carlo methods and large deviation principles. The model in use is a geometric Brownian motion under the risk-neutral measure (*see Fundamental Theorem of Asset Pricing; Risk-neutral Pricing*)

$$dS_t = rS_t dt + \sigma S_t dB_t, \quad S_0 = x \quad (15)$$

Using this model, we consider computing the probability that the process S solving equation (15) does not hit any of two barriers, a lower or an upper barrier, which are suitable, positive, twice continuously differentiable functions $(l(t), t \geq 0)$ and $(u(t), t \geq 0)$, respectively.

The approach suggested by Baldi *et al.* [5] consists in using sharp large deviations to reduce bias in **Monte Carlo simulation**. The simulation of S is done by making an equidistant partition of the time interval $[0, T]$, where T indicates the expiration of the contract. Then, the sample path is the collection

$$S_{t_{i+1}} = S_{t_i} \exp \left(\left(r - \frac{\sigma^2}{2} \right) \epsilon + \sigma (B_{t_{i+1}} - B_{t_i}) \right) \\ i = 0, 1, \dots, m \quad (16)$$

where $t_0 = 0 < t_1 < \dots < t_m = T$ and $t_{i+1} - t_i = \epsilon > 0$.

Using sharp asymptotics, it is possible to find approximations of the exit probabilities over small intervals, that is, when ϵ becomes small. Let $\varsigma \in (l(t_i), u(t_i))$ and $y \in (l(t_{i+1}), u(t_{i+1}))$. Then the approximation appears as follows:

$$p_i^\epsilon := \\ P(\exists t \in [t_i, t_{i+1}] : S_t \notin (l(t), u(t)) \mid S_{t_i} = \varsigma, S_{t_{i+1}} = y) \\ = f(t_i, \varsigma, y, \epsilon)(1 + O(\epsilon)) \quad (17)$$

where the function f is indeed known explicitly:

$$f(t, \varsigma, y, \epsilon) = \exp \left\{ -\frac{Q(t, \varsigma, y)}{\epsilon} - R(t, \varsigma, y) \right\} \quad (18)$$

with

$$Q(t, \varsigma, y) = \begin{cases} \frac{2(u(t) - \varsigma)(u(t) - y)}{\sigma^2} & \text{if } \varsigma + y > u(t) + l(t) \\ \frac{2(\varsigma - l(t))(y - l(t))}{\sigma^2} & \text{if } \varsigma + y < u(t) + l(t) \end{cases} \quad (19)$$

and

$$R(t, \varsigma, y) = \begin{cases} \frac{2(u(t) - \varsigma)u'(t)}{\sigma^2} & \text{if } \varsigma + y > u(t) + l(t) \\ \frac{2(\varsigma - l(t))l'(t)}{\sigma^2} & \text{if } \varsigma + y < u(t) + l(t) \end{cases} \quad (20)$$

The final estimator, with reduced bias, for the probability that S does not hit the barriers in the interval $[0, T]$ is constructed by simulating N independent identically distributed (i.i.d.) replications $(S^{(j)} : j \leq N)$ of the process S and obtaining

$$\frac{1}{N} \sum_{j=1}^N \prod_{i=0}^{m-1} I(S_t^{(j)} \in (l(t_i), u(t_i))) p(t_i, S_{t_i}^{(j)}, S_{t_{i+1}}^{(j)}) \quad (21)$$

where

$$p(t_i, S_{t_i}^{(j)}, S_{t_{i+1}}^{(j)}) = 1 - f(t_i, S_{t_i}^{(j)}, S_{t_{i+1}}^{(j)}, \epsilon) \quad (22)$$

Large deviations analysis can also aid the application of variance reduction techniques for Monte Carlo simulation *via* importance sampling, as is discussed next.

Importance Sampling

Once again, we concentrate on a concrete problem to illustrate the use of large deviations in the design of importance sampling (*see Variance Reduction*). Consider the problem of calculating equation (7). The optimal path equation (13) suggests a particular way in which one could bias the occurrence of the large deviations event; here we also consider time to maturity and barrier values to be large and thus we would be dealing with small probabilities (*see*

Rare-event Simulation). In particular, consider a probability measure, say $\mathbb{Q}$, under which a process $(Y(u) : 0 \leq u \leq T)$ follows a Brownian motion with drift θ_- up to time $\tau_{-a} = \inf\{s \geq 0 : Y(s) \leq -Ta\}$, and from time τ_{-a} up to time T (assuming $\tau_{-a} < T$) the drift of $Y(\cdot)$ is switched to the value θ_+ . Using the process Y , we obtain the representation

$$\alpha_T = E_{\mathbb{Q}} \left\{ I \left(\min_{0 \leq s \leq T} Y(s) \leq -aT, Y(T) > bT \right) \times h \right\} \quad (23)$$

where

$$h = e^{-\theta_- a + \theta_-^2 \tau_{-a} / 2 - \theta_+ (T - \tau_{-a}) (Y(T) + a) + \theta_+^2 (T - \tau_{-a}) / 2} \quad (24)$$

The expression above, involving the exponentials, is nothing but the likelihood ratio between the Wiener measure $\mathbb{P}$ (corresponding to the process $(B(s) : 0 \leq s \leq T)$ and the measure $\mathbb{Q}$ on the set $I(\tau_{-a} < T)$. More precisely,

$$\frac{d\mathbb{P}}{d\mathbb{Q}} I(\tau_{-a} < T) = I(\tau_{-a} < T) \times e^{-\theta_- a + \theta_-^2 \tau_{-a} / 2 - \theta_+ (T - \tau_{-a}) (Y(T) + a) + \theta_+^2 (T - \tau_{-a}) / 2} \quad (25)$$

The use of importance sampling proceeds by simulating, say, N i.i.d. replications $(Y_i : i \leq N)$ of the process $(Y(s) : 0 \leq s \leq T)$ and estimating $P(\min_{0 \leq s \leq T} B(s) \leq -a, B(T) > b)$ via

$$\alpha_T^{(N)} = \frac{1}{N} \sum_{i=1}^N I(\tau_{-a}^{(i)} < T, Y_i(T) > bT) \times h^{(i)} \quad (26)$$

where

$$h^{(i)} = e^{-\theta_- a + \theta_-^2 \tau_{-a}^{(i)} / 2 - \theta_+ (T - \tau_{-a}^{(i)}) (Y_i(T) + a) + \theta_+^2 (T - \tau_{-a}^{(i)}) / 2} \quad (27)$$

Here, $\tau_{-a}^{(i)}, i = 1, \dots, N$ are the i.i.d. replications of τ_{-a} obtained from the corresponding i.i.d. processes Y_i . Moreover, large deviations theory allows to conclude that the previous importance sampling estimator satisfies certain optimality properties as $T \nearrow \infty$ (see, for instance, [3], Ch. 7). Additional extensions of this methodology are applicable to

other types of processes. However, to design optimal importance sampling estimators, it is required to compute the associated optimal path under the corresponding rate function of the underlying process. Research in this direction has been developed recently [3, 16].

We now give a broader description of the importance sampling technique in option pricing. When pricing an option, the question is to find the expectation

$$I_g = E(g(S_t : 0 \leq t \leq T)) \quad (28)$$

where g is a payoff function (possibly path dependent) (see **Options: Basic Definitions**), and S is governed by a suitable SDE. Let us concentrate here on the geometric Brownian motion given by equation (15). The naive Monte Carlo estimator based on N replications is

$$\hat{I}_g^N = \frac{1}{N} \sum_{i=1}^N g(S_t^{(i)} : 0 \leq t \leq T) \quad (29)$$

where the $S^{(i)}$'s are i.i.d. replications ([3], a general reference on stochastic simulation) of the process S following equation (15).

The importance sampling procedure turns (28) into

$$I_g = E_{\mathbb{Q}}(g(S_t^{\phi}, 0 \leq t \leq T) \times L_T^{-1}) \quad (30)$$

where

$$\begin{aligned} dS_t^{\phi} &= (r + \sigma \phi_t) S_t^{\phi} dt + \sigma S_t^{\phi} dB_t^{\mathbb{Q}} \\ &= r S_t^{\phi} dt + \sigma S_t^{\phi} dB_t \end{aligned} \quad (31)$$

and the process $(B_t^{\mathbb{Q}} : 0 \leq t \leq T)$ is a standard Brownian motion under $\mathbb{Q}$. The relation between $B_t^{\mathbb{Q}}$ and B_t is given by

$$dB_t = \phi_t dt + dB_t^{\mathbb{Q}} \quad (32)$$

The likelihood ratio $L_T^{-1} = d\mathbb{P}/d\mathbb{Q}$ satisfies

$$\begin{aligned} L_T^{-1} &= \exp \left(- \int_0^T \phi_s dB_s + \frac{1}{2} \int_0^T \phi_s^2 ds \right) \\ &= \exp \left(- \int_0^T \phi_s dB_s^{\mathbb{Q}} - \frac{1}{2} \int_0^T \phi_s^2 ds \right) \end{aligned} \quad (33)$$

Under this specification, the importance sampling estimator takes the form

$$I_{g,IS}^N = \frac{1}{N} \sum_{i=1}^N g(S_{t,i}^\phi, 0 \leq t \leq T) L_T^{-1}(i) \quad (34)$$

where $S_{t,i}^\phi$ and $L_T^{-1}(i)$ are obtained from the corresponding i.i.d. copies of the process S^ϕ , which follows the evolution equations (31). Therefore, the ultimate problem is to find a process ϕ (which might or might not be deterministic) that guaranties an efficient estimation of I_g in terms of variance reduction. As we indicated in the simple barrier example, large deviation techniques provide tools to find such a process ϕ . In the next subsection we discuss another example.

Freidlin–Wentzel Theory

Let us suppose that we are dealing with a European option (see **Options: Basic Definitions**). Thus equation (28) becomes

$$I_g(x) = E(g(S_T) | S_0 = x) \quad (35)$$

and we write $I_g(x)$ to emphasize the dependence on the initial position.

Using **Itô's formula**, under measure $\mathbb{Q}$, the variance of $I_{g,IS}^N$ is given by

$$\begin{aligned} \text{Var}_{\mathbb{Q}}(I_{g,IS}^N) \\ = \frac{1}{N} E_{\mathbb{Q}} \left(\int_0^T L_t (\sigma I'_g(S_t^\phi) + \phi_t I_g(S_t^\phi))^2 dt \right) \end{aligned} \quad (36)$$

where I'_g is the derivative with respect to x . One can readily see that if $\phi_s = -\sigma I'_g(S_s^\phi) / I_g(S_s^\phi)$ the variance of the estimator would vanish. Unfortunately, the function $I_g(\cdot)$ is precisely what we want to find, but the idea is to find an approximation to $I_g(\cdot)$, say $\tilde{I}_g(\cdot)$, and consider $\tilde{\phi}_s = -\sigma \tilde{I}'_g(S_s^\phi) / \tilde{I}_g(S_s^\phi)$ which can be used to generate a change of measure that reduces the variance of the associated importance sampling estimator. For instance, Fourniè *et al.* [13] suggest developing a parametric expansion for $I_g(x)$ as a function of σ as $\sigma \searrow 0$. In turn, such an expansion is based, for options out of the money, on the Freidlin–Wentzel theory.

Varadhan–Laplace Principle

Recall that under the geometric Brownian motion, model (15), the path simulation at discrete-time points satisfies

$$S_{t_{i+1}} = S_{t_i} \exp \left(\left(r - \frac{\sigma^2}{2} \right) \epsilon + \sigma \sqrt{\epsilon} Z_i \right) \quad (37)$$

where $Z_i \sim N(0, 1)$ for $i = 1, \dots, n$. Let $\mathbf{Z} = (Z_1, \dots, Z_n)^\top$ ($\top$ stands for the transpose), then we denote by $G(\mathbf{Z})$ the payoff of the option under a sample $\mathbf{Z}$, for instance, for the Asian option we have $G(\mathbf{Z}) = \max \left(0, \frac{1}{n} \sum_{i=1}^n S_{t_i} - K \right)$. In this case, the partition indicates the times when the process is monitored to take the average.

The procedure developed in [14] is to change the mean of $\mathbf{Z}$ from 0 to a vector $\boldsymbol{\mu}$ to obtain an estimator of I_g . Multiplying each sample by the corresponding importance sampling weight or likelihood ratio the estimator is then

$$I_g^N = \frac{1}{N} \sum_{i=1}^N G(\mathbf{Z}^{(i)}) \exp \left(-\boldsymbol{\mu}^\top \mathbf{Z}^{(i)} + \frac{1}{2} \boldsymbol{\mu}^\top \boldsymbol{\mu} \right) \quad (38)$$

where $\mathbf{Z}^{(i)}$ is the vector $(Z_1^{(i)}, \dots, Z_n^{(i)})^\top$ of independent random variables such that $Z_j^{(i)} \sim N(\mu_j, 1)$, $j = 1, \dots, n$. The $\mathbf{Z}^{(i)}$'s, $i = 1, \dots, N$ are i.i.d. replications. To choose $\boldsymbol{\mu}$ it suffices to minimize the variance of I_g^N , which turns out to be equivalent to minimizing

$$E \left(G(\mathbf{Z})^2 \exp \left(-\boldsymbol{\mu}^\top \mathbf{Z} + \frac{1}{2} \boldsymbol{\mu}^\top \boldsymbol{\mu} \right) \right) \quad (39)$$

where $\mathbf{Z}$ here is an n -dimensional vector of i.i.d. standard Gaussian random variables. It is not an easy task to solve this optimization problem, but it can be tackled using Varadhan–Laplace asymptotics. The idea is to scale $\mathbf{Z}$ by $\sqrt{\epsilon}$ and asymptotically estimate the expectation in equation (39) as $\epsilon \rightarrow 0$. This approach makes it simpler to find the optimal $\boldsymbol{\mu}$, at least as an approximation, which is asymptotically correct in an environment of small volatility, that is, σ close to 0 in equation (15).

Another interesting application of large deviations principles is in the context of index option pricing. Consider an index H composed of m stocks $(S_1, \dots, S_m)$. The index at time t is computed as $H(t) = \sum_{i=1}^m w_i S_i$, where $w_1, \dots, w_m$ are constants.

Pricing, for instance, a European call on the index involves knowing the so-called local volatility function (see **Local Volatility Model**) of the index. What is proposed in [4] is to approximate such a function using Varadhan's principle to handle it in a simpler way, and therefore, pricing the option.

Risk Management

The use of large deviations theory for computational purposes also arises in the context of risk management. For instance, Dembo *et al.* [7] developed approximations based on large deviations theory for the tail of a loss distribution; a relevant assumption is that the individual losses are conditionally i.i.d., given the state of the economy and their identifying class (these parameters can be given by the specific industry or business line).

Credit Risk

Typically, an important task in credit risk theory (see **Credit Risk**) involves computing the distribution of losses in a portfolio composed of several debt contracts. More precisely, in a portfolio composed of n obligors, the question is to calculate the tail probability of $L_n = c_1 Y_1 + \dots + c_n Y_n$,

$$P(L_n > l) \quad (40)$$

where the Y_i 's are Bernoulli random variables such that $P(Y_i = 1) = p_i = 1 - P(Y_i = 0)$, and indicating that the i obligor (for $i = 1, \dots, n$) may or may not default. The c_i 's represent the loss resulting from the default, and l is a threshold. Generally, the number of obligors is large, and surpassing threshold l may be a rare event, which represents significant losses, in which case one may use large deviations theory to approximate the probability in equation (40). In [15] such a probability is approximated under a multifactor Gaussian copula model (see **Gaussian Copula Model**) and using large deviation theory; here we present some results that can be found in [21].

Suppose that the variables $Y_i, i = 1, \dots, n$ are triggered by other variables $X_i, i = 1, \dots, n$ that might or not be related; this is done in the following way: $Y_i = 1_{\{X_i > x_i\}}, i = 1, \dots, n$ and the vector $(X_1, \dots, X_n)$ is normally distributed. The parameters x_i are such that $P(X_i > x_i) = p_i$ for $i = 1, \dots, n$.

The correlations among variables $\{X_1, \dots, X_n\}$ are determined by the following single-factor model:

$$X_i = \rho Z + \sqrt{1 - \rho^2} Z_i, i = 1, \dots, n \quad (41)$$

where $\rho \in [0, 1)$ and $Z, Z_1, \dots, Z_n$ are independent standard normal random variables (r.v.'s).

When $\rho = 0$, there is no correlation, and using **Cramér's theorem** one can find an asymptotic formula. Suppose that $p_i = p, i = 1, \dots, n$. Then

$$\lim_{n \rightarrow \infty} \frac{1}{n} \log P(L_n > nq) = -q \ln(q/p) \ln \left(\frac{1-q}{1-p} \right) \quad (42)$$

where $l = nq$ and $q \in (p, 1)$.

When $\rho > 0$, that is, there is dependence among obligors, it is also possible to derive an asymptotic result. Indeed, if $q_n = 1 - n^{-a}$ with $a \in (0, 1)$, it is shown in [21] that

$$\lim_{n \rightarrow \infty} \frac{1}{\log n} \log P(L_n > nq_n) = -a \frac{1 - \rho^2}{\rho^2} \quad (43)$$

A more elaborate model of this type is treated in [15].

We have discussed the use of large deviations theory in several computational settings, both in pricing and in risk assessment. Another application of large deviations, also in the context of risk management, arises in the theoretical analysis of risk measures.

Risk Measures

Financial institutions are constantly worried about the quantification of the risk in their portfolios of assets: stocks, bonds, credits, and options (see **Risk Exposures**). A financial asset is generally represented by a random variable, say X , and characterized by the probability measure μ that governs the outcome of X , that is, we write $\mathcal{L}(X) = \mu$ whenever $P(X \in A) = \mu(A)$. The risk associated with X is measured by means of a so-called *risk measure* ρ , which is a real-valued function on the space of random variables that satisfies certain properties (such as monotonicity, subadditivity, positive homogeneity, and translation invariance); see [2].

Assume that it is not possible to deal with the probability measure μ directly, but instead we have independent samples $X_1, \dots, X_n$ of X . Then,

one may want to approximate $\rho(X)$ by calculating $\rho(X^{(n)})$; in this case, $X^{(n)}$ is a random variable and its law $\mathcal{L}(X^{(n)})$ is the empirical measure

$$\mu_n = \frac{1}{n} \sum_{i=1}^n \delta_{X_i} \quad (44)$$

Here δ_X stands for the Dirac measure at X .

This approach generates an error, and the question suggested in [25] is to quantify the error by considering the asymptotics, as $n \rightarrow \infty$, of

$$P(|\rho(X) - \rho(X^{(n)})| > \epsilon), \text{ for } \epsilon > 0 \quad (45)$$

Then, for positive ϵ and when $n \rightarrow \infty$, the previous quantity becomes small, and large deviation principles can be used to deal with this probability. An important result used for this is Sanov's theorem [8].

Optimal Investment

We now move to investment. Maximizing revenue in investments under a certain risk profile (which could be induced by a specific set of assets types) has been a common question for financial investors. To tackle the problem, the usual approaches are the mean–variance analysis of Markowitz (*see Risk–Return Analysis*) or the use of utility functions (*see Utility Function; Expected Utility Maximization*). Alternatively, a criterion can be set by considering asymptotic performance of the portfolio over long time horizons [1]. One has to decide how to measure such a performance, and one way to do this is by estimating, given a fixed investment policy, the probability of performing well [6, 12]. The optimization problem can be set as selecting the investment policy that minimizes the probability of ending up below a threshold or the one that maximizes the probability of surpassing it. Since the problem involves calculating an asymptotic probability, it is appealing to use large deviations techniques (one can find this approach in [19, 20, 23, 24]).

As an illustration, we describe below the method described by Pham in [19, 20]. Given an investment policy $\alpha \in \mathcal{A}$ (where $\mathcal{A}$ is the set of admissible investment policies), we consider the rate of return of the associated wealth process (i.e., the logarithm of the value of the portfolio obtained by applying the policy α). We denote such a rate of return process

by $X(\alpha) = (X_t(\alpha), t \geq 0)$. The aim is to maximize over $\mathcal{A}$ the probability $P(X_t(\alpha)/t \geq x)$ in the long term, which is the probability of a rare event as $t \rightarrow \infty$. Here, level $x \in \mathbb{R}$ represents a benchmark that an investor wants to achieve; in [6] it is considered as a stochastic benchmark, such as an index.

It is natural to attempt using large deviations theory to find a (static) policy α^* from

$$v(x, \alpha^*) := \sup_{\alpha \in \mathcal{A}} v(x, \alpha) \quad (46)$$

where

$$v(x, \alpha) = - \lim_{t \rightarrow \infty} \frac{1}{t} \log P(X_t(\alpha)/t > x) \quad (47)$$

Under regularity conditions on the drift and the volatility of the process $X_t(\alpha)$ (for instance, if the drift and diffusion coefficients are bounded and continuously differentiable), one can evaluate $v(x)$ via

$$v(x, \alpha) = \sup_{\theta} (\theta x - \Gamma(\theta, \alpha)) \quad (48)$$

where

$$\Gamma(\theta, \alpha) := \limsup_{t \rightarrow \infty} \frac{1}{t} \ln E(e^{\theta X_t(\alpha)}) \quad (49)$$

This approach is considered in [19]. For instance, if $X_t(\alpha) = \alpha Y(t)$ where $\alpha \in \mathbb{R}$ and $Y(t) = rt + \sigma B(t)$ with $r > 0$ and $B(\cdot)$ is a standard Brownian motion, we have that

$$\Gamma(\theta, \alpha) = \theta \alpha r + \frac{(\theta \alpha \sigma)^2}{2} \quad (50)$$

and then the problem is solved when $\alpha = x/r$ [21]. More sophisticated and also explicit calculations can be found in [19].
